

Bayesian networks: overview

- In this module, I'll introduce Bayesian networks, a new framework for modeling.

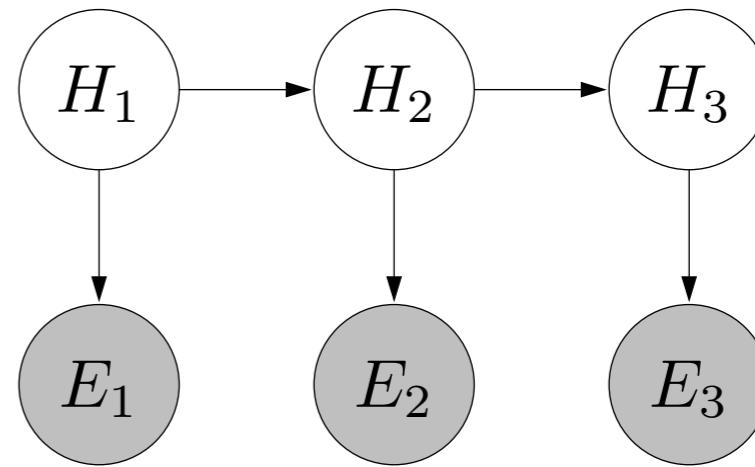

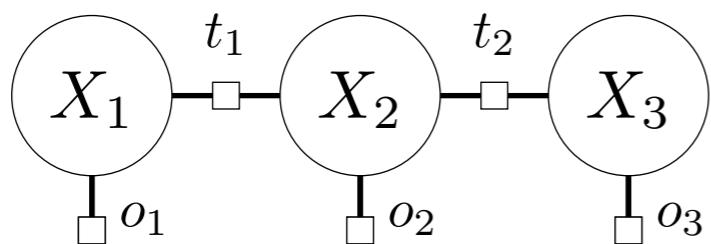

Course plan

- We have talked about two types of variable-based models.
- In constraint satisfaction problems, the objective is to find the maximum weight assignment given a factor graph.
- In Markov networks, we use the factor graph to define a joint probability distribution over assignments and compute marginal probabilities.
- Now we will present Bayesian networks, where we still define a probability distribution using a factor graph, but the factors have special meaning.
- Bayesian networks were developed by Judea Pearl in the 1980s, and have evolved into the more general notion of generative modeling that we see today.

Markov networks versus Bayesian networks

Both define a joint probability distribution over assignments

Markov networks

arbitrary factors

set of preferences

Bayesian networks

local conditional probabilities

generative process

- Before defining Bayesian networks, it is helpful to compare and contrast Markov networks and Bayesian networks at a high-level.
- Both define a joint probability distribution over assignments, and in the end, both are backed by factor graphs.
- But the way each approaches modeling is different. In Markov networks, the factors can be arbitrary, so you should think about being able to write down an arbitrary set of preferences and constraints and just throw them in. In the object tracking example, we slap on observation and transition factors.
- Bayesian networks require the factors to be a bit more coordinated with each other. In particular, they should be local conditional probabilities, which we'll define in the next module.
- We should think about a Bayesian network as defining a generative process represented by a directed graph. In the object tracking example, we think of an object as moving from position H_{i-1} to position H_i and then yielding a noisy sensor reading E_i .

Applications

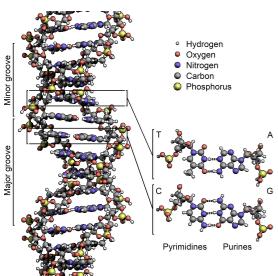

Topic modeling: unsupervised discovery of topics in text

Vision as inverse graphics: recover semantic description given image

Error correcting codes: recover data over a noisy channel

DNA matching: identify people based on relatives

- There are a huge number of applications of Bayesian networks, or more generally, generative models. One application is topic modeling, where the goal is to discover the hidden structure in a large collection of documents. For example, Latent Dirichlet Allocation (LDA) posits that each document can be described by a mixture of topics.
- Another application is a very different take on computer vision. Rather than modeling the bottom-up recognition using neural networks, which is the dominant paradigm today, we can encode the laws of physics into a graphics engine which can generate an image given a semantic description of an object. Computer vision is "just" the inverse problem: given an image, recover the hidden semantic information (e.g., objects, poses, etc.). While the "vision as inverse graphics" perspective hasn't been scaled up beyond restricted environments, the idea seems tantalizing.
- Switching gears, in a wireless or Ethernet network, nodes must send messages (a sequence of bits) to each other, but these bits can get corrupted along the way. The idea behind error correcting codes (Low-Density Parity Codes in particular) is that the sender also sends a set of random parity checks on the data bits. The receiver obtains a noisy version of the data and parity bits. A Bayesian network can then be defined to relate the original bits to the noisy bits, and the receiver can use inference (usually loopy belief propagation) to recover the original bits.
- The final application that we'll discuss is DNA matching. For example, Bonaparte is a software tool developed in the Netherlands that uses Bayesian networks to match DNA based on a candidate's family members. There are two use cases, the first one is controversial and the second one is grim. The first use case is in forensics: given DNA found at a crime site, even if the suspect's DNA is not in the database, one can match it against the family members of a suspect, where the Bayesian network is structured according to the family tree of the suspect and models the relationship between the family members's DNA using Mendelian inheritance. While this technology has been used to solve crime cases, there are some tricky ethical concerns about this expanded DNA matching, especially since an individual's decision to release their own DNA can impact the privacy of family members. The second use case is in disaster victim identification. After a big airplane crash (e.g., Malaysia Airlines flight MH17 in the Ukraine in 2014), a victim's DNA found at the crash site can be matched against their family members using the same mechanism above to identify the victim.

Why Bayesian networks?

- Handle **heterogenously** missing information, both at training and test time
- Incorporate **prior** knowledge (e.g., Mendelian inheritance, laws of physics)
- Can **interpret** all the intermediate variables
- Precursor to **causal** models (can do interventions and counterfactuals)

- These days, it's hard not to think about problems exclusively through the lens of standard supervised learning such as training a deep neural network on a pile of data.. Bayesian networks operate in a different paradigm which offers several advantages that are important to understand so that you can pick the right tool for the task.
- First, in traditional machine learning (e.g., linear models or neural networks), the input is usually of a fixed size (homogenous). With Bayesian networks, the types of inputs one can handle can be **heterogeneous** (e.g., missing features), both during training and test times.
- Second, Bayesian networks offer most leverage when you have rich **prior knowledge** (e.g., Mendelian inheritance, laws of physics). This allows one to often learn from very few samples and extrapolate beyond distribution of the training data. In contrast, deep neural networks generally require much more data to be effective.
- Third, because Bayesian networks are often carefully constructed based on prior knowledge, the variables in the Bayesian network are **interpretable** (more so than hidden units in a neural network), and you can ask questions about any of them via the laws of probability.
- Finally, Bayesian networks are an important precursor to developing **causal** models, which allow us to answer questions about interventions ("what would happen if we gave this drug to this patient?") and counterfactuals ("what would have happened if we had given this drug?"). These are extremely tricky and deep questions that standard machine learning or any methods that only view the world through prediction are unable to answer. For an easy introduction to some of these ideas, check out Judea Pearl's *The Book of Why*.
- Finally, Bayesian networks aren't suitable in every situation. In many vision, speech, and language problems, we have large datasets, mostly care about prediction, and it is extremely hard to incorporate prior knowledge about these very complex domains. In such cases, Bayesian networks have largely been supplanted with deep learning.

Roadmap

Modeling

Definitions

Probabilistic programming

Inference

Probabilistic inference

Forward-backward

Particle filtering

Learning

Supervised learning

Smoothing

EM algorithm

- In the remaining modules on Bayesian networks, I will first introduce a formal definition of Bayesian networks and explore some of its formal properties. Then I'll talk about probabilistic programming, a way to define Bayesian networks as (probabilistic) programs, which will provide a new perspective that allows to develop more powerful models.
- Then we turn to inference, which is what we do once we have a Bayesian network. We first define probabilistic inference, the problem of computing conditional and marginal probabilities and reduce this to the problem of inference in Markov networks. We then specialize to Hidden Markov Models (HMMs), an important special case of Bayesian networks, and show that the **forward-backward** algorithm can leverage the graph structure and do exact inference efficiently. Then we introduce particle filtering, which allows us to do approximate inference but scale up to HMMs where variables have larger domains.
- Finally, we talk about learning Bayesian networks from data. First we show how to do **supervised learning**, where all the variables are observed, which turns out to be very easy (just count and normalize). Then we show how to guard against overfitting in Bayesian networks by **smoothing**. Finally, we show how to do learning where some of the variables are unobserved using the **EM algorithm**.

Review: probability

Random variables: sunshine $S \in \{0, 1\}$, rain $R \in \{0, 1\}$

Joint distribution (probabilistic database):

| s | r | $\mathbb{P}(S = s, R = r)$ |
|-----|-----|----------------------------|
| 0 | 0 | 0.20 |
| 0 | 1 | 0.08 |
| 1 | 0 | 0.70 |
| 1 | 1 | 0.02 |

Marginal distribution:

(aggregate rows)

| s | $\mathbb{P}(S = s)$ |
|-----|---------------------|
| 0 | 0.28 |
| 1 | 0.72 |

Conditional distribution:

(select rows, normalize)

| s | $\mathbb{P}(S = s R = 1)$ |
|-----|-----------------------------|
| 0 | 0.8 |
| 1 | 0.2 |

- Before introducing Bayesian networks, let's review some basic probability. We start with an example about the weather. Suppose we have two boolean random variables, S and R representing whether there is sunshine and whether there is rain, respectively. Think of an assignment to (S, R) as representing a possible state of the world.
- The **joint distribution** specifies a probability for each assignment to (S, R) (state of the world). We use lowercase letters (e.g., s and r) to denote values and uppercase letters (e.g., S and R) to denote random variables. Note that $\mathbb{P}(S = s, R = r)$ is a probability (a number) while $\mathbb{P}(S, R)$ is a distribution (represented by a table of probabilities). We don't know what state of the world we're in, but we know what the probabilities are (there are no unknown unknowns). Think of the joint distribution as one giant (probabilistic) database that contains full information about how the world works.
- Sometimes, we might only be interested in a subset of the variables, e.g., sunshine S . From the joint distribution, we can derive a **marginal distribution** over that. In the case of S , we get this by summing the probabilities of the rows in the joint distribution table that share the same value of S . The interpretation is that we are interested in (the marginal probability of) S . We don't explicitly care about R , but we still need to take into account R 's effect on S . We say in this case that R is **marginalized out**.
- Sometimes, we might observe evidence; for example, suppose we know that there's rain ($R = 1$). Again from the joint distribution, we can derive a **conditional distribution** of the remaining variables (S) given this evidence $R = 1$. We do this by selecting rows of the table matching the condition and then normalizing the remaining probabilities so that they sum to 1. Note that this normalization constant is exactly $\mathbb{P}(R = 1)$.

Review: probability

Variables: S (sunshine), R (rain), T (traffic), A (autumn)

Joint distribution (probabilistic database):

$$\mathbb{P}(S, R, T, A)$$

Marginal conditional distribution (probabilistic inference):

- **Condition** on evidence (traffic, autumn): $T = 1, A = 1$
- Interested in **query** (rain?): R

$$\mathbb{P}(\underbrace{R}_{\text{query}} \mid \underbrace{T = 1, A = 1}_{\text{condition}})$$

(S is **marginalized out**)

- Let us augment our running example with two other random variables, T (whether there is traffic) and A (whether it's autumn).
- We have a joint distribution, which again can be thought of as a probabilistic database that tells us how the world works.
- Probabilistic inference is the process of answering questions against this database. In general, we can both condition on evidence and be interested in a subset of the remaining variables at the same time.
- For example, we might **condition** on there being traffic and the fact that it's autumn.
- And we might be interested in whether there is rain (called the **query** variable), marginalizing out **sunshine**.
- The set of conditioning variables, query variables, and variables that are marginalized out should form a partitioning of all the variables.

A puzzle

Problem: earthquakes, burglaries, and alarms

Earthquakes and **burglaries** are independent events (probability ϵ).

Either will cause an **alarm** to go off.

Suppose you get an **alarm**.

Does hearing that there's an **earthquake** increase, decrease, or keep constant the probability of a **burglary**?

Joint distribution:

$$\mathbb{P}(E, B, A)$$

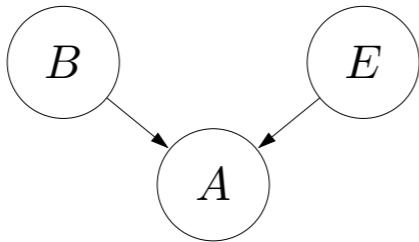

Questions:

$$\mathbb{P}(B = 1 \mid A = 1) \quad ? \quad \mathbb{P}(B = 1 \mid A = 1, E = 1)$$

- Let's consider a classic puzzle, which we will tackle with Bayesian networks. Suppose that in the world, earthquakes and burglaries are independent (and hopefully rare) events, and for the sake of simplicity, assume that each one has a probability ϵ (say 0.05) of happening. You have installed an alarm that will notify you if either one happens.
- Now suppose you are away on vacation and you get an alarm notification on your phone. You would expect at this point that the probability of your home being burglarized has gone up. But suppose then you see breaking news saying that there was an earthquake near your home. How does that change your beliefs about the burglary?
- One could try to intuit the answer, but this is risky because sometimes the right answer is counterintuitive. In this case, you might think since earthquakes and burglaries are independent, that the probability shouldn't change. But that would be wrong. So let's use Bayesian networks instead to perform this type of **reasoning under uncertainty** in a principled way.
- Let us try to write down this question using the language of probability. The first step is to always figure out the variables of interest, which in this case are earthquake E , burglary B , and alarm A .
- We then have a joint distribution over these variables, which we will define later. But first the questions. We are interested in comparing the probability of a burglary given an alarm only versus given alarm and earthquake.

Bayesian network (alarm)

| b | p(b) |
|---|----------------|
| 1 | ϵ |
| 0 | $1 - \epsilon$ |

| e | p(e) |
|---|----------------|
| 1 | ϵ |
| 0 | $1 - \epsilon$ |

| b | e | a | $p(a b, e)$ |
|---|---|---|---------------|
| 0 | 0 | 0 | 1 |
| 0 | 0 | 1 | 0 |
| 0 | 1 | 0 | 0 |
| 0 | 1 | 1 | 1 |
| 1 | 0 | 0 | 0 |
| 1 | 0 | 1 | 1 |
| 1 | 1 | 0 | 0 |
| 1 | 1 | 1 | 1 |

$$p(b) = \epsilon \cdot [b = 1] + (1 - \epsilon) \cdot [b = 0]$$

$$p(e) = \epsilon \cdot [e = 1] + (1 - \epsilon) \cdot [e = 0]$$

$$p(a | b, e) = [a = (b \vee e)]$$

$$\mathbb{P}(B = b, E = e, A = a) \stackrel{\text{def}}{=} p(b)p(e)p(a | b, e)$$

- Now let us define the joint distribution. Recall the first step was just to define the three variables, B (burglary), E (earthquake), and A (alarm).
- Second, we connect up the variables to model the dependencies. Unlike in factor graphs, these dependencies are represented as **directed** edges. You can intuitively think about the directionality as representing causality, though what this actually means is a more complex issue and beyond the scope of this module.
- Third, for each variable, we specify a **local conditional distribution** of that variable given its parent variables. In this example, B and E have no parents while A has two parents, B and E . This local conditional distribution is what governs how a variable is generated.
- Fourth, we define the joint distribution over all the random variables as the product of all the local conditional distributions.
- Note that we write the local conditional distributions using p , while \mathbb{P} is reserved for the joint distribution over all random variables, which is defined as the product.

Probabilistic inference (alarm)

Joint distribution

| b | e | a | $\mathbb{P}(B = b, E = e, A = a)$ |
|-----|-----|-----|-----------------------------------|
| 0 | 0 | 0 | $(1 - \epsilon)^2$ |
| 0 | 0 | 1 | 0 |
| 0 | 1 | 0 | 0 |
| 0 | 1 | 1 | $(1 - \epsilon)\epsilon$ |
| 1 | 0 | 0 | 0 |
| 1 | 0 | 1 | $\epsilon(1 - \epsilon)$ |
| 1 | 1 | 0 | 0 |
| 1 | 1 | 1 | ϵ^2 |

Questions:

$$\mathbb{P}(B = 1) = \epsilon(1 - \epsilon) + \epsilon^2 = \epsilon$$

$$\mathbb{P}(B = 1 \mid A = 1) = \frac{\epsilon(1 - \epsilon) + \epsilon^2}{\epsilon(1 - \epsilon) + \epsilon^2 + (1 - \epsilon)\epsilon} = \frac{1}{2 - \epsilon}$$

$$\mathbb{P}(B = 1 \mid A = 1, E = 1) = \frac{\epsilon^2}{\epsilon^2 + (1 - \epsilon)\epsilon} = \epsilon$$

[demo]

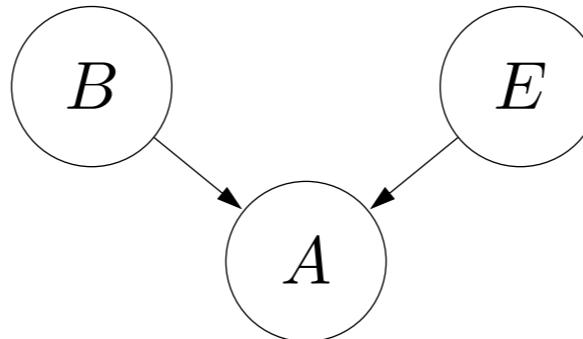

News flash: earthquakes decrease burglaries!*

*This is not a causal statement!

- We multiply all the local conditional distributions together to produce the joint distribution. Recall this is the probabilistic that is the source of all truth, and from it we can answer all sorts of questions.
- Let us start with the simplest query, $\mathbb{P}(B = 1)$: what is the probability of burglary without any evidence? We can sum up all the rows with $B = 1$ to get ϵ .
- Now suppose we hear the alarm $A = 1$. Let us first filter out all the rows where $A = 1$ does not hold. Then we look at the sum of the probabilities of rows where $B = 1$ over the sum of all the probabilities. The resulting probability of burglary is now $\mathbb{P}(B = 1 | A = 1) = \frac{1}{2-\epsilon}$.
- Now let us condition on alarm ($A = 1$) and earthquake ($E = 1$). Filter out rows that don't satisfy the condition, and look at the fraction of probabilities of remaining rows on $B = 1$. The resulting probability of burglary goes **down** to $\mathbb{P}(B = 1 | A = 1, E = 1) = \epsilon$ again.
- So in the end, observing that there's an earthquake does actually decrease the probability of the burglary. This might be counterintuitive because we said that burglaries and earthquakes are independent. But it's important to not interpret this causally. Creating more earthquakes clearly will not make the burglars disappear. When dealing with slippery questions such as these, we need a sound mathematical framework like Bayesian networks to ensure that we get the right answers.

Explaining away

Key idea: explaining away

Suppose two causes positively influence an effect. Conditioned on the effect, further conditioning on one cause reduces the probability of the other cause.

$$\mathbb{P}(B = 1 \mid A = 1, E = 1) < \mathbb{P}(B = 1 \mid A = 1)$$

Note: happens even if causes are independent!

- This last phenomenon is so important for reasoning under uncertainty that it has a special name: **explaining away**. Suppose we have two **cause** variables B and E , which are parents of an **effect** variable A . Further, assume the causes influence the effect positively (e.g., through the OR function).
- Let us condition on the evidence $A = 1$. We are trying to seek an explanation for $A = 1$ (what caused the alarm to go off?).
- Further conditioning on one of the causes ($E = 1$) decreases the probability of the other cause, because $E = 1$ alone **explains away** $A = 1$, and there's no more pressure on B .
- Note that in our setting, the probability of $B = 1$ returns to the original $\mathbb{P}(B = 1)$, but this need not be the case in general.
- Conditioning on $A = 1$ is important for explaining away. If you didn't, then the probability of $B = 1$ would not change. You can verify for yourself that $\mathbb{P}(B = 1 | E = 1) = \mathbb{P}(B = 1)$, which just follows from the definition of B and E being independent.

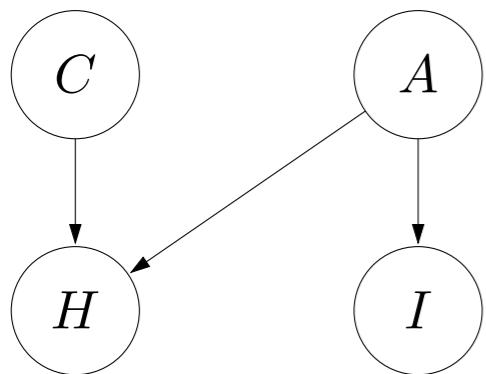

Medical diagnosis

Problem: cold or allergies?

You are coughing and have itchy eyes. Do you have a cold?

Random variables:

cold C , allergies A , cough H , itchy eyes I

Joint distribution:

$$\mathbb{P}(C = c, A = a, H = h, I = i) = p(c)p(a)p(h \mid c, a)p(i \mid a)$$

Questions:

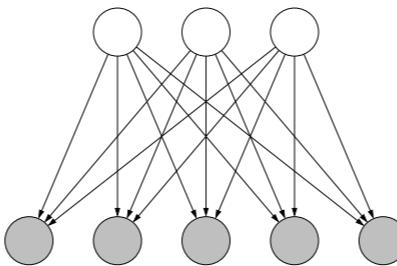

$$\mathbb{P}(C = 1 \mid H = 1) = 0.28$$

$$\mathbb{P}(C = 1 \mid H = 1, I = 1) = 0.13$$

[demo]

- Here is another example (a cartoon version of Bayesian networks for medical diagnosis).
- Step 1: identify all the relevant variables.
- Step 2: draw arrows between them, using prior knowledge. Using our simplistic medical knowledge, suppose that a cough can be either because of a cold or because of allergies, but itchy eyes are generally only caused by allergies.
- Step 3: define a local conditional distribution for each variable.
- Step 4: multiply all the local conditional distributions to form the joint distribution.
- Now we have our probabilistic database and we can ask questions about it. Our motivating question is $\mathbb{P}(C, A \mid H = 1, I = 1)$.
- You can try the demo to get a quantitative answer. Note that $\mathbb{P}(C = 1 \mid H = 1) = 0.28$, which is another example of explaining away. Observing itchy eyes provides evidence for A , which explains away the cough ($H = 1$), resulting in a reduced probability of cold ($C = 1$).
- Note that even qualitatively reasoning about even a four-node Bayesian network can be quite subtle, let alone getting quantitative answers on large Bayesian networks. But we can rest at ease since the laws of probability make sure that all these calculations are internally consistent provided we defined the Bayesian network correctly (which in practice is an admittedly hard modeling task).

Bayesian network (definition)

Definition: Bayesian network

Let $X = (X_1, \dots, X_n)$ be random variables.

A **Bayesian network** is a directed acyclic graph (DAG) that specifies a **joint distribution** over X as a product of **local conditional distributions**, one for each node:

$$\mathbb{P}(X_1 = x_1, \dots, X_n = x_n) \stackrel{\text{def}}{=} \prod_{i=1}^n p(x_i \mid x_{\text{Parents}(i)})$$

- Without further ado, let's define a Bayesian network formally. A Bayesian network defines a joint distribution over a set of random variables.
- Second, we have a directed **acyclic** graph over the variables that captures the qualitative dependencies.
- Third, we specify a local conditional distribution for each variable X_i , which is a function that specifies a distribution over X_i given an assignment $x_{\text{Parents}(i)}$ to its parents in the graph (possibly no parents).
- Finally, the joint distribution is simply **defined** to be the product of all of the local conditional distributions.
- Notationally, we use lowercase p (in $p(x_i | x_{\text{Parents}(i)})$) to denote a local conditional distribution, and uppercase \mathbb{P} to denote the induced joint distribution over all variables. While we will see that the two coincide, it is important to keep these things separate in your head!

Probabilistic inference (definition)

Input

Bayesian network: $\mathbb{P}(X_1, \dots, X_n)$

Evidence: $E = e$ where $E \subseteq X$ is subset of variables

Query: $Q \subseteq X$ is subset of variables

Output

$$\mathbb{P}(Q | E = e) \longleftrightarrow \mathbb{P}(Q = q | E = e) \text{ for all values } q$$

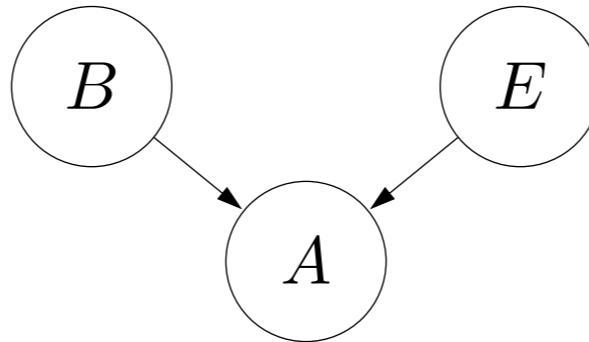

Example: if coughing and itchy eyes, have a cold?

$$\mathbb{P}(C | H = 1, I = 1)$$

- Now given a Bayesian network representing a probabilistic database, we can answer questions on it.
- In particular, we are given a set of evidence variables E and values e . We are also given a set of query variables Q . What a probabilistic inference algorithm should output given this is the marginal conditional distribution $\mathbb{P}(Q | E = e)$.
- Note that this output is a table that specifies a probability for each assignment of values to Q .
- So far, we have shown examples of probabilistic inference on small Bayesian networks. The bad news is that in general, answering arbitrary probabilistic inference questions on arbitrary Bayesian networks is computationally intractable. The good news is that the core probabilistic inference in Bayesian networks is identical to Markov networks (which we will see later).

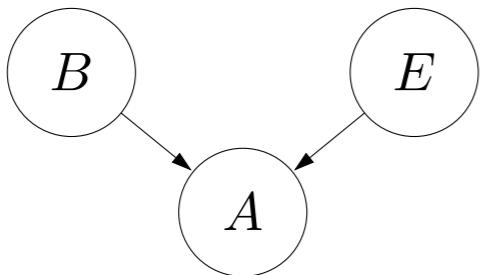

Summary

- Random variables capture state of world
- Directed edges between variables represent dependencies
- Local conditional distributions \Rightarrow joint distribution
- Probabilistic inference: ask questions about world
- Captures reasoning patterns (e.g., explaining away)

- In summary, we have introduced Bayesian networks.
- It's important to think about an assignment to random variables as capturing the state of the world.
- Directed edges represent qualitative (sometimes causal) dependencies.
- Quantitatively, we specify a local conditional distribution for each variable conditioned on its parents, and multiply them together to get a joint distribution.
- Now we have our probabilistic database on which we can ask all sorts of questions, marginal conditional probabilities.
- Hopefully through the alarm and medical diagnosis examples, you are able to appreciate that the framework can capture intuitive or counter-intuitive reasoning patterns such as explaining away in a mathematically sound way so you can sleep well at night.

Probabilistic programs

Joint distribution:

$$\mathbb{P}(B = b, E = e, A = a) = p(b)p(e)p(a \mid b, e)$$

Probabilistic program: alarm

$$B \sim \text{Bernoulli}(\epsilon)$$

$$E \sim \text{Bernoulli}(\epsilon)$$

$$A = B \vee E$$

```
def Bernoulli(epsilon):  
    return random.random() < epsilon
```

Key idea: probabilistic program

A randomized program that sets the random variables.

- Recall that a Bayesian network is given by (i) a set of random variables, (ii) directed edges between those variables capturing qualitative dependencies, (iii) local conditional distributions of each variable given its parents which captures these dependencies quantitatively, and (iv) a joint distribution which is produced by multiplying all the local conditional distributions together. Now the joint distribution is your probabilistic database, which you can answer all sorts of questions on it using probabilistic inference.
- There is another way of writing down Bayesian networks other than graphically or mathematically, and that is as a probabilistic program.
- Let's go through the alarm example. We can sample B and E independently from a Bernoulli distribution with parameter ϵ , which produces 1 (true) with probability ϵ . Then we just set $A = B \vee E$.
- In general, a **probabilistic program** is a randomized program that invokes a random number generator. Executing this program will assign values to a collection of random variables X_1, \dots, X_n ; that is, generating an assignment.
- We then define probability under the joint distribution of an assignment to be exactly the probability that the program generates an assignment.
- While you can run the probabilistic program to generate samples, it's important to think about it as a mathematical construct that is used to define a joint distribution.

Probabilistic program: example

Probabilistic program: object tracking

$$X_0 = (0, 0)$$

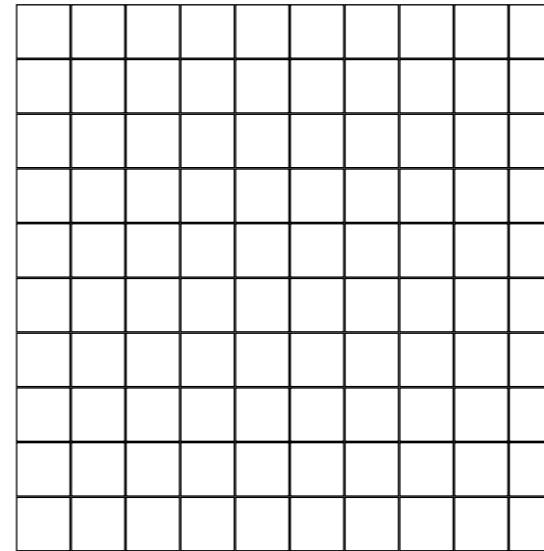

For each time step $i = 1, \dots, n$:

if Bernoulli(α):

$$X_i = X_{i-1} + (1, 0) \text{ [go right]}$$

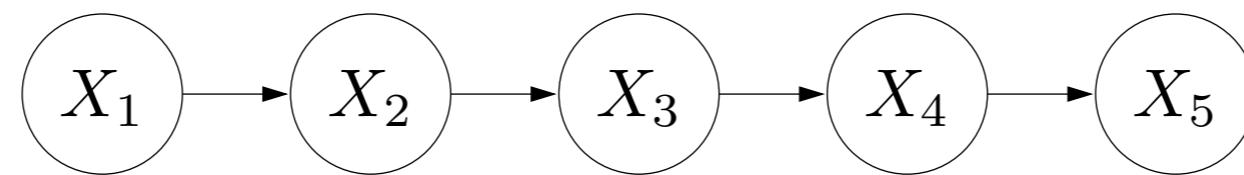

else:

$$X_i = X_{i-1} + (0, 1) \text{ [go down]}$$

(press ctrl-enter to save)

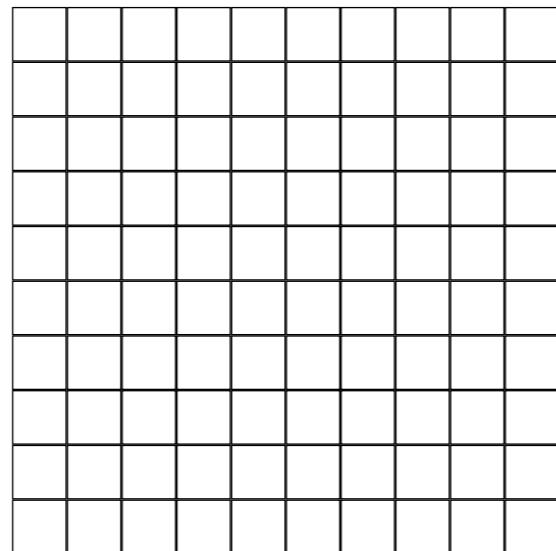

Run

- This is a more interesting example showcasing the convenience of probabilistic **programming**.
- In this program, we'll use a for loop, which allows us to compactly specify the distribution over an unboundedly large (n) set of variables.
- In the object tracking example, we define a program that generates the trajectory of an object. At each time step i , we take the previous X_{i-1} location and move it right with probability α and down with probability $1 - \alpha$, yielding X_i .
- This program is a full specification of the local conditional distribution and thus the joint distribution!
- Try clicking [Run] to run the program. Each time a new assignment of (X_1, \dots, X_n) is chosen, and recall that the probability of the program generating an assignment is the probability under the joint distribution by definition.
- We can also draw the Bayesian network, which allows us to visualize the dependencies. Here, each X_i only depends on X_{i-1} . This chain-structured Bayesian network is called a **Markov model**. However, note that the graphical representation doesn't specify the local conditional distributions.

Probabilistic inference: example

Question: what are possible trajectories given **evidence** $X_{10} = (8, 2)$?

(press ctrl-enter to save)

Run

- Having used the program to define a joint distribution, we can now answer questions about that distribution.
- For example, suppose that we observe evidence $X_{10} = (8, 2)$. What is the distribution over the other variables?
- In the demo, we condition on the evidence and observe the distribution over all trajectories, which are constrained to go through $(8, 2)$ at time step 10.

Application: language modeling

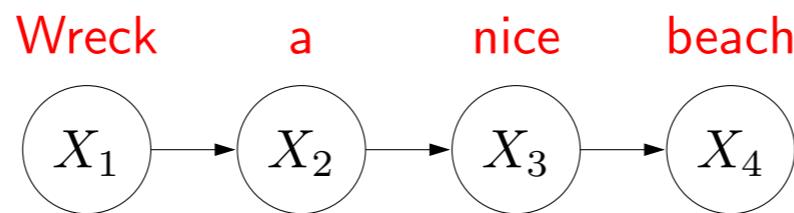

Can be used to score sentences for speech recognition or machine translation

Probabilistic program: Markov model

For each position $i = 1, 2, \dots, n$:

Generate word $X_i \sim p(X_i | X_{i-1})$

- Now I'm going to quickly go through a set of examples of Bayesian networks or probabilistic programs and talk about the applications they are used for.
- A natural language sentence can be viewed as a sequence of words, and a language model assigns a probability to each sentence, which measures the "goodness" of that sentence.
- Markov models and higher-order Markov models (called n -gram models in NLP), were the dominant paradigm for language modeling before deep learning, and for a while, they outperformed neural language models since they were computationally much easier to scale up.
- While they could be used to generate text unconditionally, they were often used in the context of a speech recognition or machine translation system to score the fluency of the output.
- A Markov model generates each word given the previous word according to some local conditional distribution $p(X_i | X_{i-1})$ which we're not specifying right now.

Application: object tracking

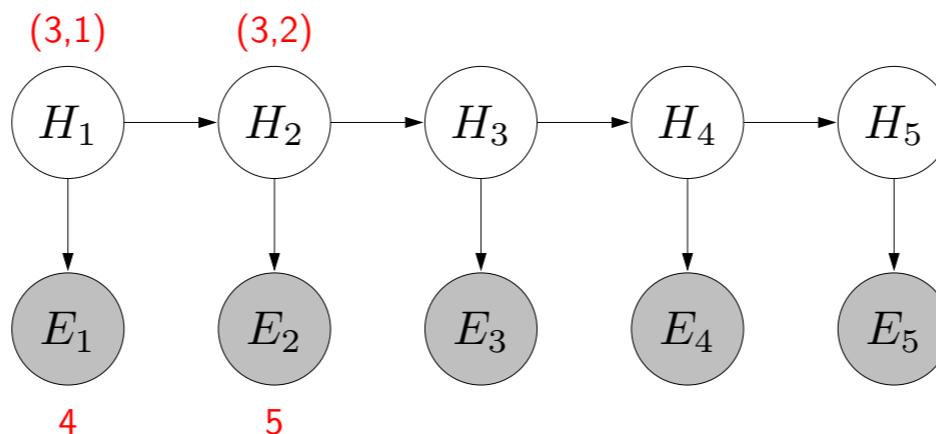

Probabilistic program: hidden Markov model (HMM)

For each time step $t = 1, \dots, T$:

Generate object location $H_t \sim p(H_t | H_{t-1})$

Generate sensor reading $E_t \sim p(E_t | H_t)$

Inference: given sensor readings, where is the object?

- Markov models are limiting because they do not have a way of talking about noisy evidence (sensor readings). They can be extended to hidden Markov models, which introduce a parallel sequence of observation variables.
- For example, in object tracking, H_t denotes the true object location, and E_t denotes the noisy sensor reading, which might be (i) the location H_t plus noise, or (ii) the distance from H_t plus noise, depending on the type of sensor.
- In speech recognition, H_t would be the phonemes or words and E_t would be the raw acoustic signal.

Application: multiple object tracking

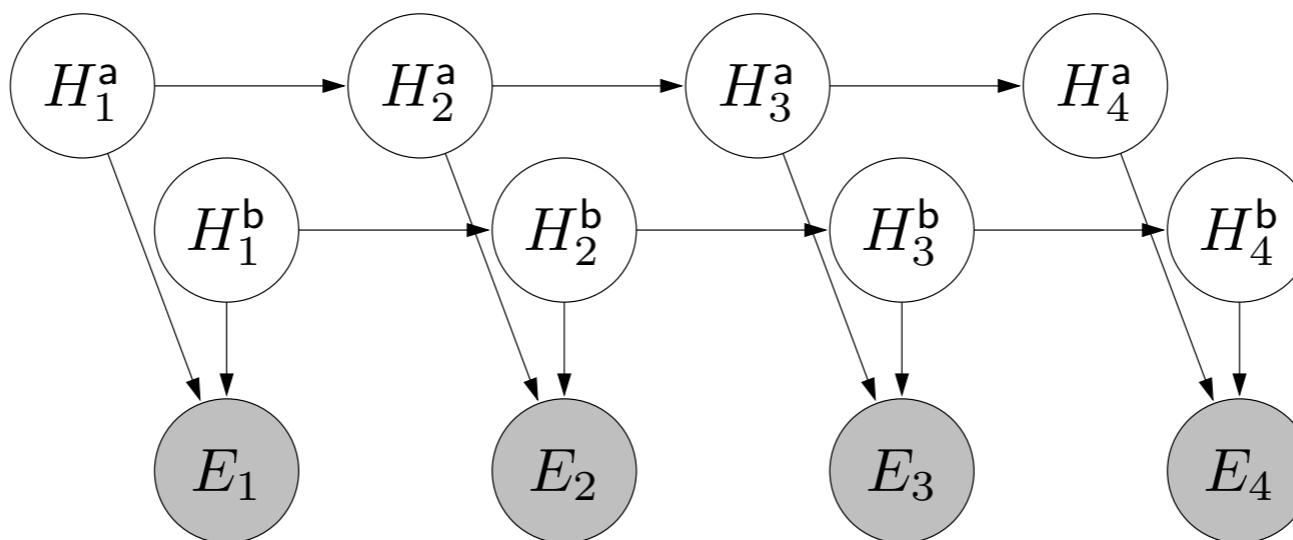

Probabilistic program: factorial HMM

For each time step $t = 1, \dots, T$:

For each object $o \in \{a, b\}$:

Generate location $H_t^o \sim p(H_t^o \mid H_{t-1}^o)$

Generate sensor reading $E_t \sim p(E_t \mid H_t^a, H_t^b)$

- An extension of an HMM, called a **factorial HMM**, can be used to track multiple objects.
- We assume that each object moves independently according to a Markov model, but that we get one sensor reading which is some noisy aggregated function of the true positions.
- For example, E_t could be the set $\{H_t^a, H_t^b\}$, which reveals where the objects are, but doesn't say which object is responsible for which element in the set.

Application: document classification

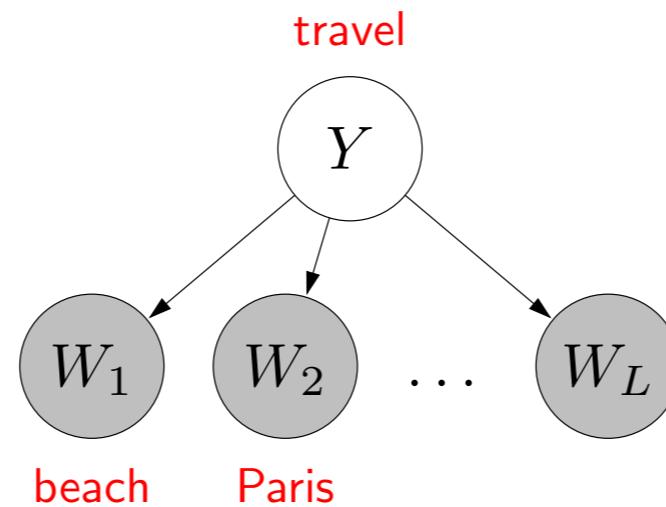

Probabilistic program: naive Bayes

Generate label $Y \sim p(Y)$

For each position $i = 1, \dots, L$:

Generate word $W_i \sim p(W_i | Y)$

Inference: given a text document, what is it about?

- Naive Bayes is a very simple model which is often used for classification. For document classification, we generate a label and all the words in the document given that label.
- Note that the words are all generated independently, which is not a very realistic model of language, but naive Bayes models are surprisingly effective for tasks such as document classification.
- These types of models are traditionally called generative models as opposed to discriminative models for classification. Rather than thinking about how you take the input and produce the output label (e.g., using a neural network), you go the other way around: think about how the input is generated from the output (which is usually the purer, more structured form of the input).
- One advantage of using Naive Bayes for classification is that "training" is extremely easy and fast and just requires counting (as opposed to performing gradient descent).

Application: topic modeling

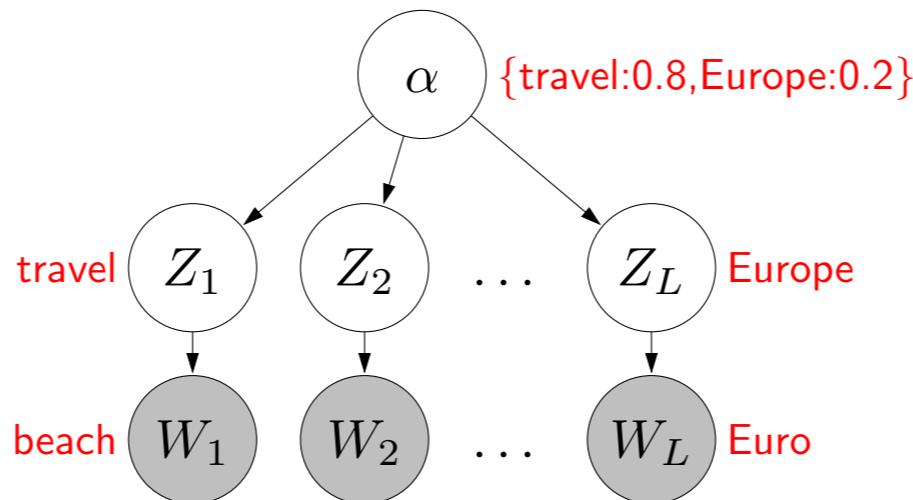

Probabilistic program: latent Dirichlet allocation

Generate a distribution over topics $\alpha \in \mathbb{R}^K$

For each position $i = 1, \dots, L$:

Generate a topic $Z_i \sim p(Z_i | \alpha)$

Generate a word $W_i \sim p(W_i | Z_i)$

Inference: given a text document, what topics is it about?

- A more sophisticated model of text is Latent Dirichlet Allocation (LDA), which allows a document to not just be about one topic or class (which was true in naive Bayes), but about multiple topics.
- Here, the distribution over topics α is chosen per document from a Dirichlet distribution. Note that α is a continuous-valued random variable. For each position, we choose a topic according to that per-document distribution and generate a word given that topic.
- Latent Dirichlet Allocation (LDA) has been very influential for modeling not only text but images, videos, music, etc.; any sort of data with hidden structure. It is very related to matrix factorization.

Application: medical diagnosis

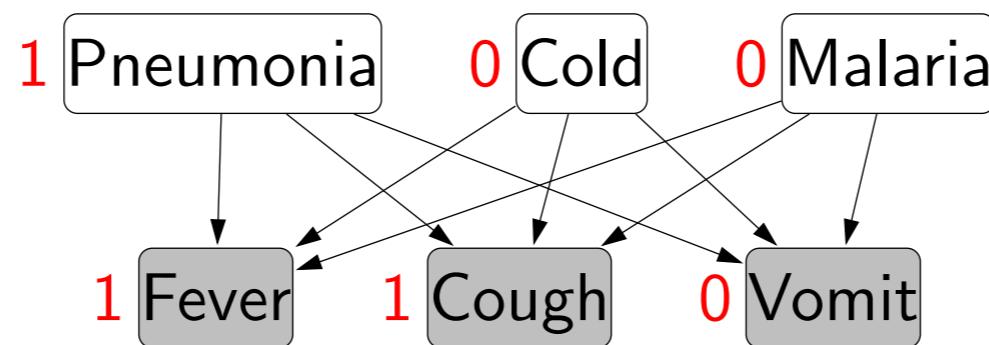

Probabilistic program: diseases and symptoms

For each disease $i = 1, \dots, m$:

 Generate activity of disease $D_i \sim p(D_i)$

For each symptom $j = 1, \dots, n$:

 Generate activity of symptom $S_j \sim p(S_j | D_{1:m})$

Inference: If a patient has some symptoms, what diseases do they have?

- We already saw a special case of this model. In general, we would like to diagnose many diseases and might have measured many symptoms and vitals.

Application: social network analysis

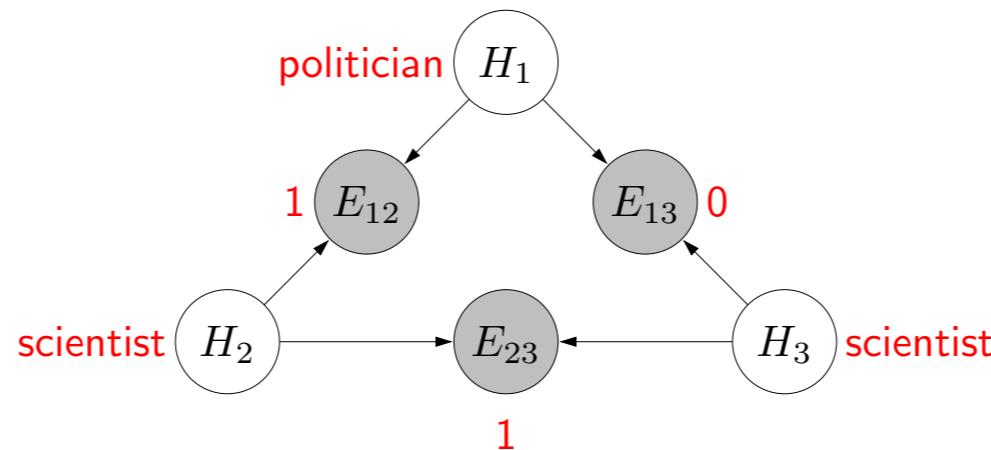

Probabilistic program: stochastic block model

For each person $i = 1, \dots, n$:

Generate person type $H_i \sim p(H_i)$

For each pair of people $i \neq j$:

Generate connectedness $E_{ij} \sim p(E_{ij} \mid H_i, H_j)$

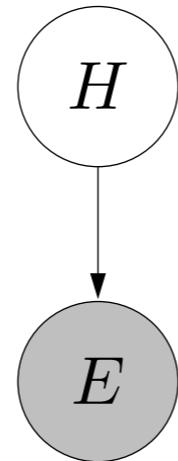

Inference: Given a social network graph, what types of people are there?

- One can also model graphs such as social networks. A very naive-Bayes-like model is that each node (person) has a "type". Whether two people interact with each other (there is an edge between the two people) is determined solely by their types and random chance.
- Note: there are extensions called mixed membership models which, like LDA, allow each person to have multiple types.

Summary

- Probabilistic program specifies a Bayesian network
- Many different types of models
- Common paradigm: come up with stories of how the quantities of interest (output) generate the data (input)
- Opposite of how we normally do classification!

- In summary, we've seen how we can define Bayesian networks (and therefore joint distributions) by writing down probabilistic programs.
- Using this powerful tool, we then did a whirlwind tour of lots of probabilistic programs that exist in the literature (though not often introduced under this general framework).
- The common theme of these probabilistic programs is that each attempts to produce **stories** of how certain quantities of interest H (e.g., actual location of an object) generate (or give rise to) observations E (e.g., usually noisy versions).
- After defining such a model, one can do probabilistic inference to compute $\mathbb{P}(H | E = e)$. Note that we can see how Bayesian networks allow us to handle heterogeneous inputs (e.g., missing information). We can simply condition on partial evidence.
- Bayesian networks therefore provide quite a different paradigm compared to normal classification (e.g., neural networks). You have to think about going from the output to the input rather than input to output, which takes some getting used to.

Review: Bayesian network

Random variables:

cold C , allergies A , cough H , itchy eyes I

Joint distribution:

$$\mathbb{P}(C = c, A = a, H = h, I = i) = p(c)p(a)p(h \mid c, a)p(i \mid a)$$

Definition: Bayesian network

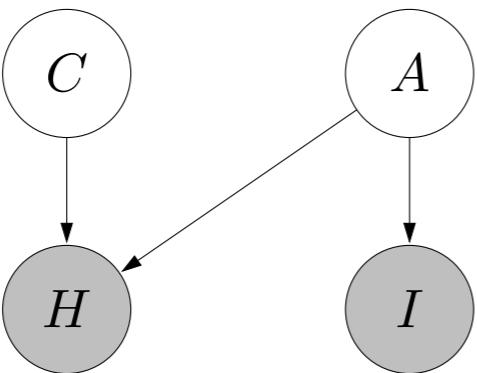

Let $X = (X_1, \dots, X_n)$ be random variables.

A **Bayesian network** is a directed acyclic graph (DAG) that specifies a **joint distribution** over X as a product of **local conditional distributions**, one for each node:

$$\mathbb{P}(X_1 = x_1, \dots, X_n = x_n) \stackrel{\text{def}}{=} \prod_{i=1}^n p(x_i \mid x_{\text{Parents}(i)})$$

- Recall that a Bayesian network is given by (i) a set of random variables, (ii) directed edges between those variables capturing qualitative dependencies, (iii) local conditional distributions of each variable given its parents which captures these dependencies quantitatively, and (iv) a joint distribution which is produced by multiplying all the local conditional distributions together.

Review: probabilistic inference

Question: $\mathbb{P}(C \mid H = 1, I = 1)$

Input

Bayesian network: $\mathbb{P}(X_1, \dots, X_n)$

Evidence: $E = e$ where $E \subseteq X$ is subset of variables

Query: $Q \subseteq X$ is subset of variables

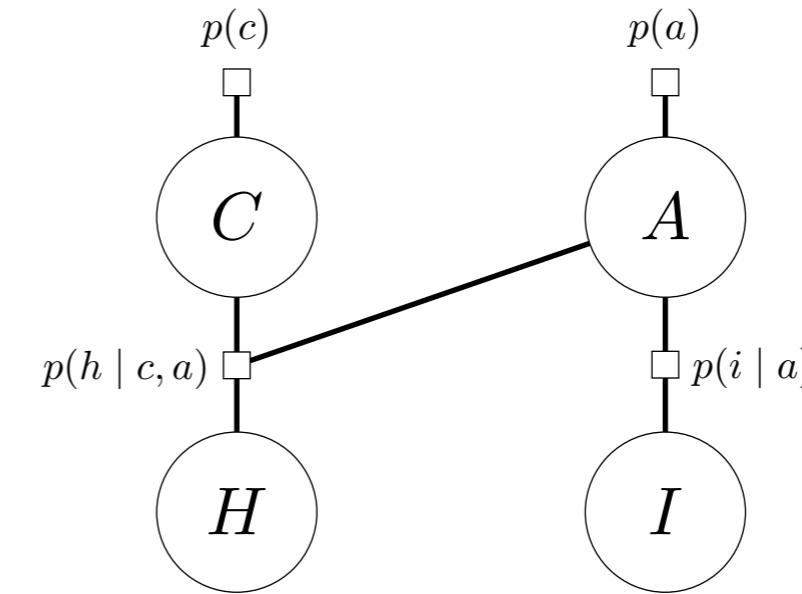

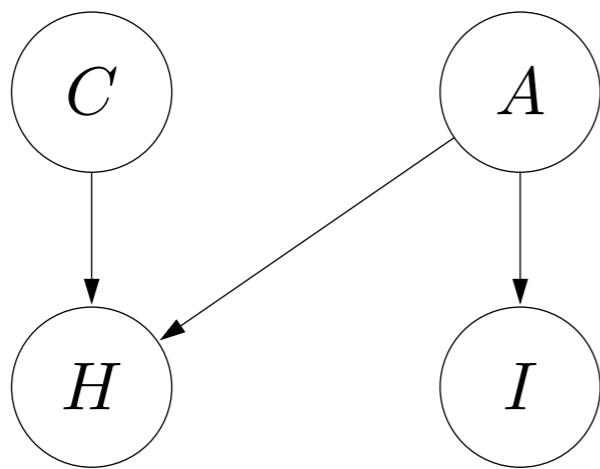

Output

$\mathbb{P}(Q \mid E = e) \longleftrightarrow \mathbb{P}(Q = q \mid E = e)$ for all values q

- Given the joint distribution representing your probabilistic database, you can answer all sorts of questions on it using probabilistic inference.
- Given a set of evidence variables and values, a set of query variables, we want to compute the probability of the query variables given the evidence, marginalizing out all other variables.

Reduction to Markov networks

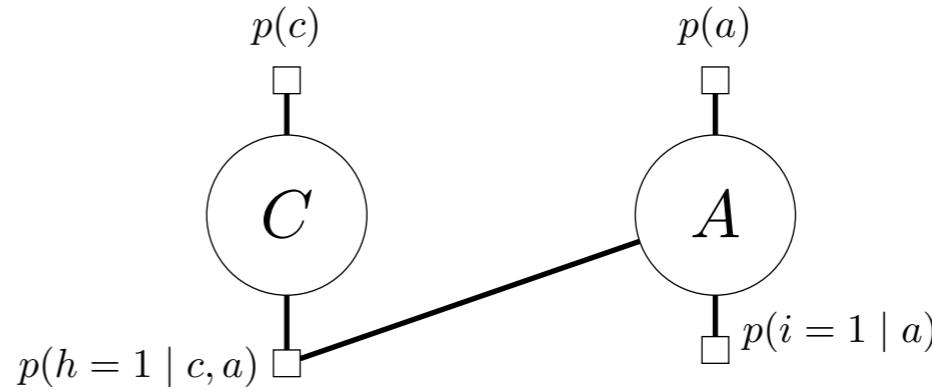

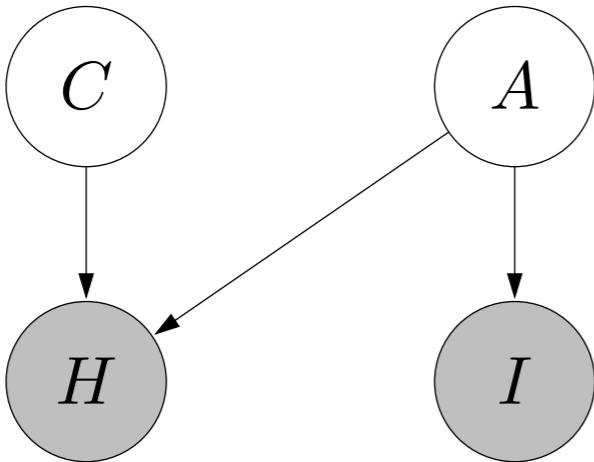

$$\mathbb{P}(C = c, A = a, H = h, I = i) = \frac{1}{Z} p(c)p(a)p(h | c, a)p(i | a)$$

Bayesian network = Markov network with normalization constant $Z = 1$

Reminder: single factor that connects **all** parents!

- Our overarching strategy for performing inference in Bayesian networks is to convert them into Markov networks.
- Recall that the joint distribution is just the product of all the local conditional distributions. The local conditional distributions (e.g., $p(a | b, e)$) are all non-negative so they can be interpreted as simply factors in a factor graph.
- Recall that a Markov network defines the joint distribution as the product of all the factors divided by some normalization constant Z . But in this case, $Z = 1$ because the factors are local conditional distributions of a Bayesian network! Put it another way, Bayesian networks are just instances of Markov networks where the normalization constant $Z = 1$.
- It's important to remember that there is a single factor that connects all the parents. Don't let the directed graph in the Bayesian network deceive you into thinking that there are two factors, one per arrow, which is a common mistake.
- Now we can run any inference algorithm for Markov networks (e.g., Gibbs sampling) on this so-called Markov network and obtain quantities such as $\mathbb{P}(H = 1)$. But there is one important thing that's missing, which is the ability to condition on evidence...

Conditioning on evidence

Markov network:

$$\mathbb{P}(C = c, A = a \mid H = 1, I = 1) = \frac{1}{Z} p(c)p(a)p(h = 1 \mid c, a)p(i = 1 \mid a)$$

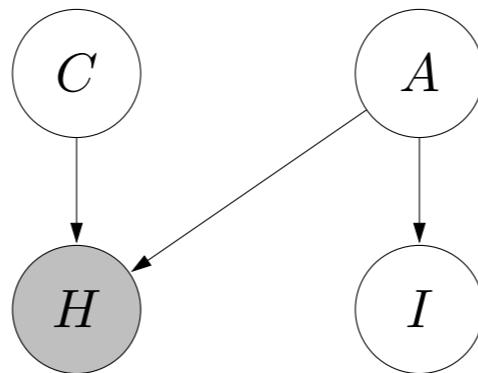

Bayesian network with evidence = Markov network with $Z = \mathbb{P}(H = 1, I = 1)$

Solution: run any inference algorithm for Markov networks (e.g., Gibbs sampling)!

[demo]

- Suppose we condition on evidence $H = 1$ and $I = 1$.
- We can define a new Markov network over the remaining variables (C and A) by simply plugging in the values to H and I . The normalization constant Z is the sum over all values of C and A , which is no longer 1, but rather the probability of the evidence $\mathbb{P}(H = 1, I = 1)$.
- To understand why this relationship holds, recall that the desired conditional probability is the joint probability over the marginal probability. The factors simply represent the joint probability, and thus the normalization constant must be the marginal probability.
- Now we can again run any inference algorithm for Markov networks (e.g., Gibbs sampling), and this allows us to do probabilistic inference in any Bayesian network.
- In the demo, we will run Gibbs sampling to compute $\mathbb{P}(C = 1 \mid H = 1, I = 1)$, and we see that it converges to the right answer (0.13).

Leveraging additional structure: unobserved leaves

Markov network:

$$\mathbb{P}(\textcolor{orange}{C} = c, \textcolor{orange}{A} = a, \textcolor{orange}{I} = i \mid H = 1) = \frac{1}{Z} p(\textcolor{orange}{c}) p(\textcolor{orange}{a}) p(h = 1 \mid \textcolor{orange}{c}, \textcolor{orange}{a}) p(\textcolor{orange}{i} \mid \textcolor{orange}{a}),$$

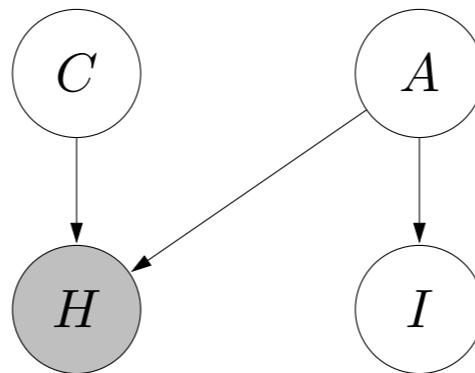

where $Z = \mathbb{P}(H = 1)$

Question: $\mathbb{P}(C = 1 \mid H = 1)$

Can we reduce the Markov network before running inference?

- We could stop there, but there are two more ways we can leverage the structure of Bayesian networks to optimize things a bit.
- Suppose we are now just conditioning on $H = 1$. As before we can form a Markov network over the remaining variables.
- But what if we knew we were only interested in $\mathbb{P}(C = 1 \mid H = 1)$?
- Is there a way to reduce the size of the Markov network before running inference?

Leveraging additional structure: unobserved leaves

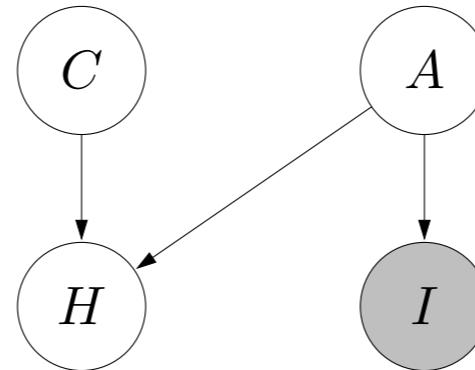

Markov network:

$$\begin{aligned}\mathbb{P}(C = c, A = a \mid H = 1) &= \sum_i \mathbb{P}(C = c, A = a, I = i \mid H = 1) \\ &= \sum_i \frac{1}{Z} p(c)p(a)p(h = 1 \mid c, a)p(i \mid a) \\ &= \frac{1}{Z} p(c)p(a)p(h = 1 \mid c, a) \sum_i p(i \mid a) \\ &= \frac{1}{Z} p(c)p(a)p(h = 1 \mid c, a)\end{aligned}$$

Throw away any unobserved leaves before running inference!

- The answer is yes.
- Let us try marginalizing out I . We expand using the definition of marginal probability, definition of the Bayesian network, pushing the \sum_i inwards past factors that don't depend on i , and noting that $\sum_i p(i | a) = 1$ by definition of local conditional distributions.
- But if we stare at the last equation, it is what we would have gotten if we had just ignored I in the first place!
- The general principle here is that marginalization of any unobserved leaf node produces 1, and thus all such nodes can be simply ignored. And we can keep on iterating this until all leaves are observed.
- This is practically very useful because it means that whenever we have a large Bayesian network, we might be able to remove large swaths of the network.
- This property establishes a bridge between marginalization (algebraic operations, usually involves hard work) with removal (graph operations, usually more intuitive).

Leveraging additional structure: independence

Markov network:

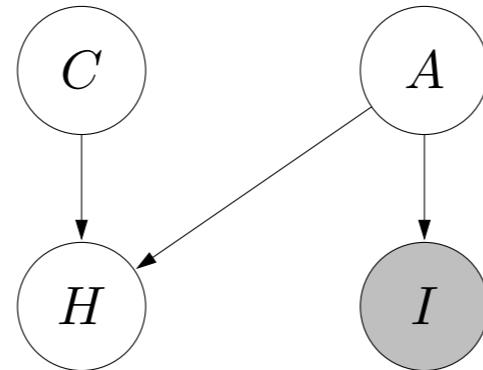

$$\begin{aligned}\mathbb{P}(\textcolor{orange}{C} = \textcolor{orange}{c} \mid I = 1) &= \sum_{a,h} \mathbb{P}(\textcolor{orange}{C} = \textcolor{orange}{c}, A = a, H = h \mid I = 1) \\ &= \sum_{a,h} \frac{1}{Z} p(\textcolor{orange}{c}) p(a) p(h \mid \textcolor{orange}{c}, a) p(i = 1 \mid a) \\ &= \sum_a \frac{1}{Z} p(\textcolor{orange}{c}) p(a) p(i = 1 \mid a) \\ &= p(\textcolor{orange}{c}) \sum_a \frac{1}{Z} p(a) p(i = 1 \mid a) \\ &= p(\textcolor{orange}{c})\end{aligned}$$

Throw away any disconnected components before running inference!

- There is another type of structure we can exploit, which is not specific to Bayesian networks, but shows up generally in Markov networks.
- Suppose we now condition on $I = 1$. Let us expand the marginal probability into the joint probability, expand into the local conditional probabilities, marginalize out the unobserved leaf H using the same idea we just discussed,
- Now at this point, C is completely disconnected from A and I . Algebraically, we can pull $p(c)$ out of the expression.
- We have this mess involving a and i , but this quantity does not depend on c so it is a constant. In this case, we know this constant must be 1 because both $p(c)$ and the LHS are probability distributions.
- So we can throw away any disconnected components. Note that it is advantageous to do this after removing all unobserved leaves, because removing those leaves can help disconnect the graph, as it did in this example.
- Now we have a Markov network, and we would run a standard inference algorithm on it. But in this case, it only has one factor which is already a local probability distribution, so we're done.

Summary

- Condition on evidence (e.g., $I = 1$)
- Throw away unobserved leaves (e.g., H)
- Throw away disconnected components (e.g., A and I)
- Define Markov network out of remaining factors
- Run your favorite inference algorithm (e.g., manual, Gibbs sampling)

- In summary, we tackled the problem of how to perform probabilistic inference in Bayesian networks, by reducing the problem to that of inference in Markov networks.
- To prepare the Markov network, we condition on the evidence (substitute the values into the factors), throw away any unobserved leaves, and throw away any disconnected components.
- Then we just define the Markov network over the remaining factors. If the resulting Markov network is small enough, we can do inference manually. Otherwise, we can run an algorithm like Gibbs sampling.

Hidden Markov models for object tracking

| h_1 | $p(h_1)$ |
|-------|----------|
| 0 | $1/3$ |
| 1 | $1/3$ |
| 2 | $1/3$ |

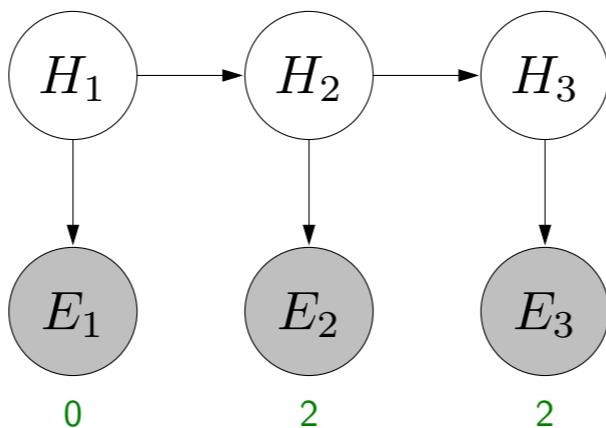

| h_i | $p(h_i h_{i-1})$ |
|---------------|--------------------|
| $h_{i-1} - 1$ | $1/4$ |
| h_{i-1} | $1/2$ |
| $h_{i-1} + 1$ | $1/4$ |

| e_i | $p(e_i h_i)$ |
|-----------|----------------|
| $h_i - 1$ | $1/4$ |
| h_i | $1/2$ |
| $h_i + 1$ | $1/4$ |

$$\mathbb{P}(H = h, E = e) = \underbrace{p(h_1)}_{\text{start}} \prod_{i=2}^n \underbrace{p(h_i | h_{i-1})}_{\text{transition}} \prod_{i=1}^n \underbrace{p(e_i | h_i)}_{\text{emission}}$$

- Let us revisit our object tracking example, now through the lens of HMMs. Recall that each time i , an object is at a location H_i , and what we observe is a noisy observation E_i . The goal is to infer where the object is / was.
- We define a probabilistic story as follows: An object starts at H_1 uniformly drawn over all possible locations.
- Then at each subsequent time step, the object **transitions** from the previous time step, keeping the same location with 1/2 probability, and moves to an adjacent location each with 1/4 probability. For example, if $p(h_3 = 3 | h_2 = 3) = 1/2$ and $p(h_3 = 2 | h_2 = 3) = 1/4$.
- At each time step, we also **emit** a sensor reading E_i given the actual location H_i , following the same process as transitions (1/2 probability of the same location, 1/4 probability of an adjacent location).
- Recall that finally, we define a joint distribution over all the actual locations H_1, \dots, H_n and sensor readings E_1, \dots, E_n by taking the product of all the local conditional probabilities.

Inference questions

Question (**filtering**):

$$\mathbb{P}(H_2 \mid E_1 = 0, E_2 = 2)$$

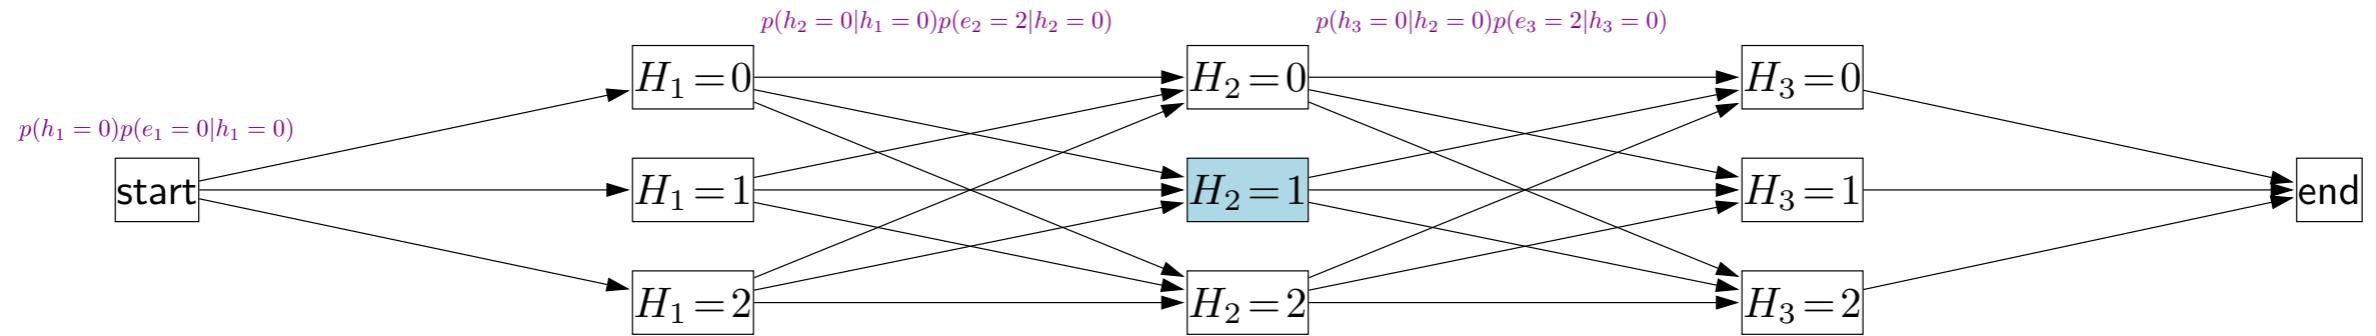

Question (**smoothing**):

$$\mathbb{P}(H_2 \mid E_1 = 0, E_2 = 2, E_3 = 2)$$

Note: filtering is a special case of smoothing if marginalize unobserved leaves

- In principle, you could ask any type of questions on an HMM, but there are two common ones: filtering and smoothing.
- **Filtering** asks for the distribution of some hidden variable H_i conditioned on only the evidence up until that point. This is useful when you're doing real-time object tracking, and you can't see the future.
- **Smoothing** asks for the distribution of some hidden variable H_i conditioned on all the evidence, including the future. This is useful when you have collected all the data and want to retrospectively go and figure out what H_i was.
- Note that filtering is a special case of smoothing: if we're asking for H_i given E_1, \dots, E_i , then we can marginalize everything in the future (since they are just unobserved leaf nodes), reducing the problem to a smaller HMM, where we are smoothing.

Lattice representation

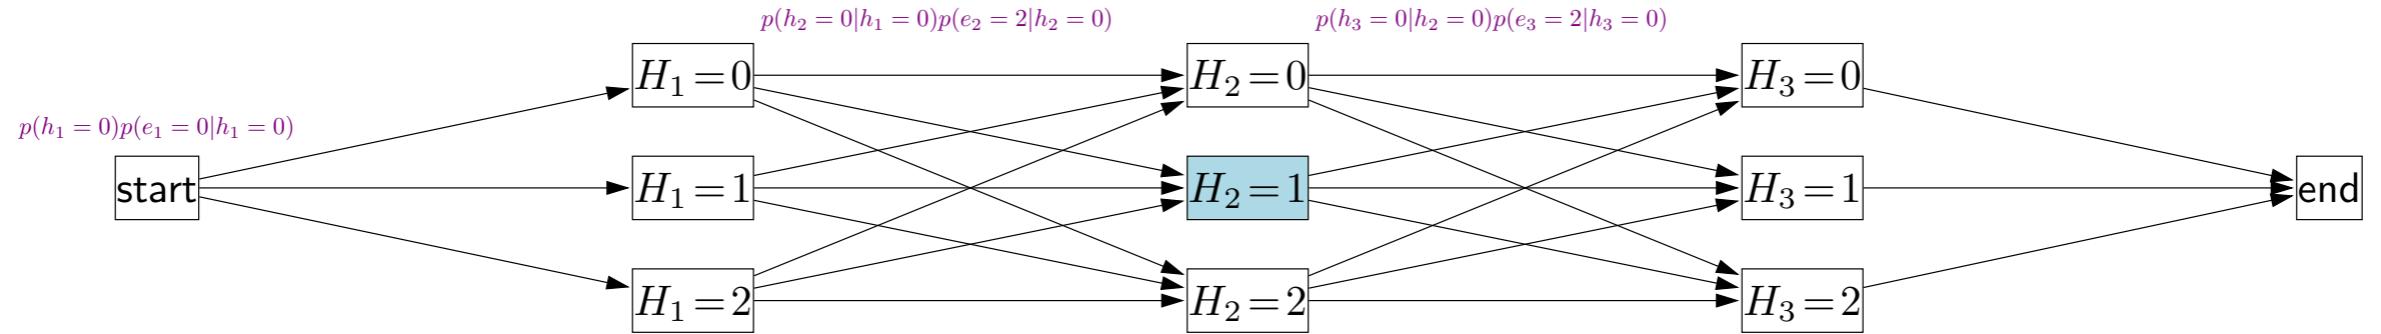

- Edge $\boxed{\text{start}} \Rightarrow \boxed{H_1 = h_1}$ has weight $p(h_1)p(e_1 | h_1)$
- Edge $\boxed{H_{i-1} = h_{i-1}} \Rightarrow \boxed{H_i = h_i}$ has weight $p(h_i | h_{i-1})p(e_i | h_i)$
- Each path from $\boxed{\text{start}}$ to $\boxed{\text{end}}$ is an assignment with weight equal to the product of edge weights

Key: $\mathbb{P}(H_i = h_i | E = e)$ is the weighted fraction of paths through $\boxed{H_i = h_i}$

- The forward-backward algorithm is based on a form of dynamic programming.
- To develop this, we consider a **lattice representation** of HMMs. Consider a directed graph (not to be confused with the HMM) with a start node, an end node, and a node for each assignment of a value to a variable $H_i = v$. The nodes are arranged in a lattice, where each column corresponds to one variable H_i and each row corresponds to a particular value v . Each path from the start to the end corresponds exactly to a complete assignment to the nodes.
- Each edge has a weight (a single number) determined by the local conditional probabilities (more generally, the factors in a factor graph). For each edge into $H_i = h_i$, we multiply by the transition probability into h_i and emission probability $p(e_i | h_i)$.
- This defines a weight for each path (assignment) in the graph equal to the joint probability $P(H = h, E = e)$.
- Note that the lattice contains $O(n|\text{Domain}|)$ nodes and $O(n|\text{Domain}|^2)$ edges, where n is the number of variables and $|\text{Domain}|$ is the number of values in the domain of each variable (3 in our example).
- Now comes the key point. Recall we want to compute a smoothing question $\mathbb{P}(H_i = h_i | E = e)$. This quantity is simply the weighted fraction of paths that pass through $H_i = h_i$. This is just a way of visualizing the definition of the smoothing question.
- There are an exponential number of paths, so it's intractable to enumerate all of them. But we can use dynamic programming...

Forward and backward messages

Forward: $F_i(h_i) = \sum_{h_{i-1}} F_{i-1}(h_{i-1}) \text{Weight}([H_{i-1} = h_{i-1}], [H_i = h_i])$

sum of weights of paths from $\boxed{\text{start}}$ to $\boxed{H_i = h_i}$

Backward: $B_i(h_i) = \sum_{h_{i+1}} B_{i+1}(h_{i+1}) \text{Weight}([H_i = h_i], [H_{i+1} = h_{i+1}])$

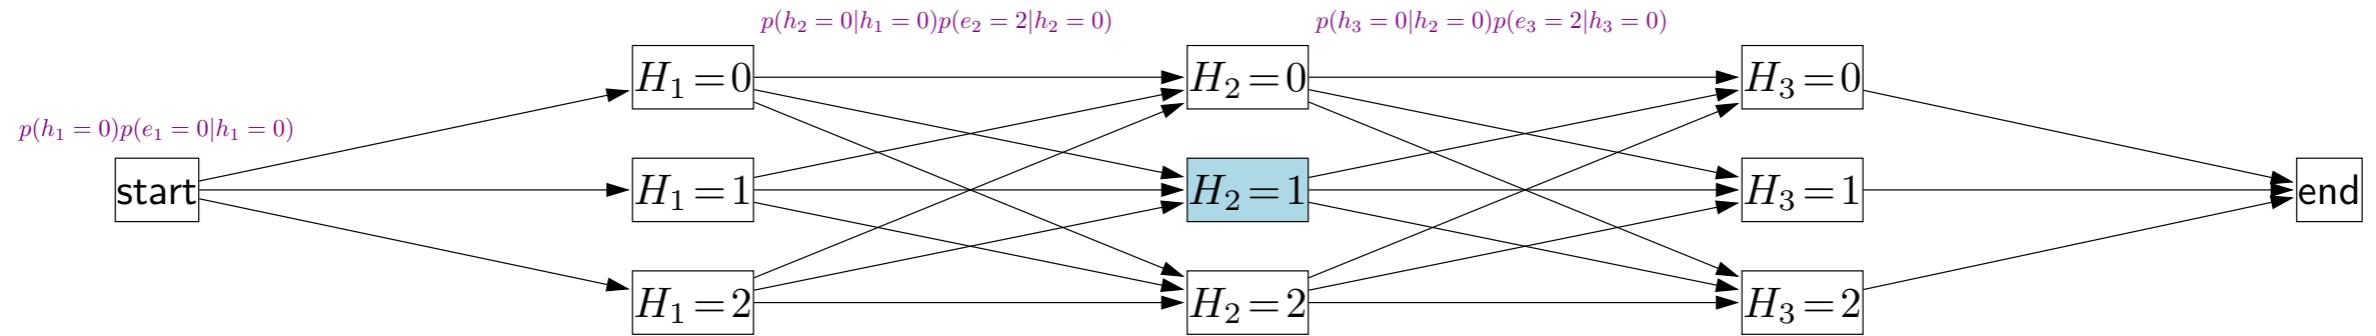

sum of weights of paths from $\boxed{H_i = h_i}$ to $\boxed{\text{end}}$

Define $S_i(h_i) = F_i(h_i)B_i(h_i)$:

sum of weights of paths from $\boxed{\text{start}}$ to $\boxed{\text{end}}$ through $\boxed{H_i = h_i}$

- First, define the forward message $F_i(v)$ to be the sum of the weights over all paths from the start node to $H_i = v$. This can be defined recursively: any path that goes $H_i = h_i$ will have to go through some $H_{i-1} = h_{i-1}$, so we can sum over all possible values of h_{i-1} .
- Analogously, let the backward message $B_i(v)$ be the sum of the weights over all paths from $H_i = v$ to the end node.
- Finally, define $S_i(v)$ to be the sum of the weights over all paths from the start node to the end node that pass through the intermediate node $X_i = v$. This quantity is just the product of the weights of paths going into $H_i = h_i$ ($F_i(h_i)$) and those leaving it ($B_i(h_i)$).
- This is analogous to factoring: $(a + b)(c + d) = ab + ad + bc + bd$.
- Note: $F_1(h_1) = p(h_1)p(e_1 = 0 \mid h_1)$ and $B_n(h_n) = 1$ are base cases, which don't require the recurrence.

Putting everything together

$$\mathbb{P}(H_i = h_i \mid E = e) = \frac{S_i(h_i)}{\sum_v S_i(v)}$$

 **Algorithm: forward-backward algorithm**

Compute F_1, F_2, \dots, F_n
Compute B_n, B_{n-1}, \dots, B_1
Compute S_i for each i and normalize

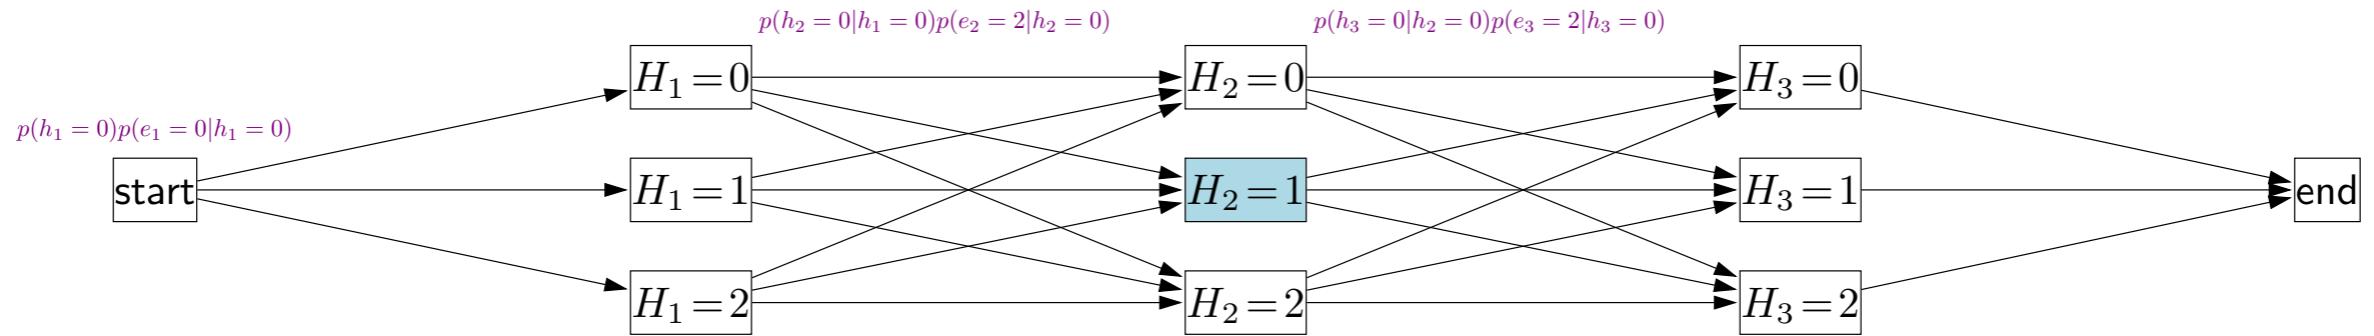

Running time: $O(n|\text{Domain}|^2)$

[demo]

- Now the smoothing question $\mathbb{P}(H_i = h_i \mid E = e)$ is just equal to the normalized version of S_i .
- The algorithm is thus as follows: for each node $H_i = h_i$, we compute three numbers: $F_i(h_i), B_i(h_i), S_i(h_i)$. First, we sweep forward to compute all the F_i 's recursively. At the same time, we sweep backward to compute all the B_i 's recursively. Then we compute S_i by pointwise multiplication.
- The running time of the algorithm is $O(n|\text{Domain}|^2)$, which is the number of edges in the lattice.
- In the demo, we are running the variable elimination algorithm, which is a generalization of the forward-backward algorithm for arbitrary Markov networks. As you step through the algorithm, you can see that the algorithm first computes a forward message F_2 and then a backward message B_2 , and then it multiplies everything together and normalizes to produce $\mathbb{P}(H_2 \mid E_1 = 0, E_2 = 2, E_3 = 2)$. The names and details don't match up exactly, so you don't need to look too closely.
- Implementation note: we technically can normalize S_i to get $\mathbb{P}(H_i \mid E = e)$ at the very end but it's useful to normalize F_i and B_i at each step to avoid underflow. In addition, normalization of the forward messages yields $\mathbb{P}(H_i = v \mid E_1 = e_1, \dots, E_i = e_i)$ which are exactly the filtering queries!

Summary

- **Lattice representation:** paths are assignments
- **Dynamic programming:** compute sums efficiently
- **Forward-backward algorithm:** compute all smoothing questions, share intermediate computations

- In summary, we have presented the forward-backward algorithm for probabilistic inference in HMMs, in particular smoothing queries.
- The algorithm is based on the lattice representation in which each path is an assignment, and the weight of path is the joint probability.
- Smoothing is just then asking for the weighted fraction of paths that pass through a given node.
- Dynamic programming can be used to compute this quantity efficiently.
- This is formalized using the forward-backward algorithm, which consists of two sets of recurrences.
- Note that the forward-backward algorithm gives you the answer to all the smoothing questions ($\mathbb{P}(H_i = h_i \mid E = e)$ for all i), because the intermediate computations are all shared.

Review: Hidden Markov models for object tracking

| h_1 | $p(h_1)$ |
|-------|----------|
| 0 | $1/3$ |
| 1 | $1/3$ |
| 2 | $1/3$ |

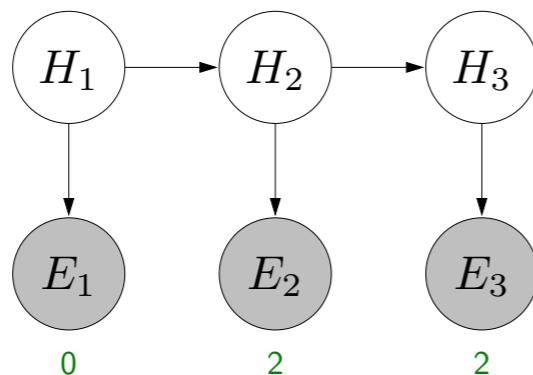

| h_i | $p(h_i h_{i-1})$ |
|---------------|--------------------|
| $h_{i-1} - 1$ | $1/4$ |
| h_{i-1} | $1/2$ |
| $h_{i-1} + 1$ | $1/4$ |

| e_i | $p(e_i h_i)$ |
|-----------|----------------|
| $h_i - 1$ | $1/4$ |
| h_i | $1/2$ |
| $h_i + 1$ | $1/4$ |

$$\mathbb{P}(H = h, E = e) = \underbrace{p(h_1)}_{\text{start}} \prod_{i=2}^n \underbrace{p(h_i | h_{i-1})}_{\text{transition}} \prod_{i=1}^n \underbrace{p(e_i | h_i)}_{\text{emission}}$$

- Recall that HMM for object tracking.
- At each point in time, an object has a position H_i , which gives rise to a sensor reading E_i . We start with H_1 uniform over positions, transition from H_{i-1} to H_i with 1/2 probability on the same location and 1/4 probability on an adjacent location. We emit the sensor reading analogously. Multiply everything together to form the joint distribution over locations H_1, \dots, H_n and sensor readings E_1, \dots, E_n .

Review: inference in Hidden Markov models

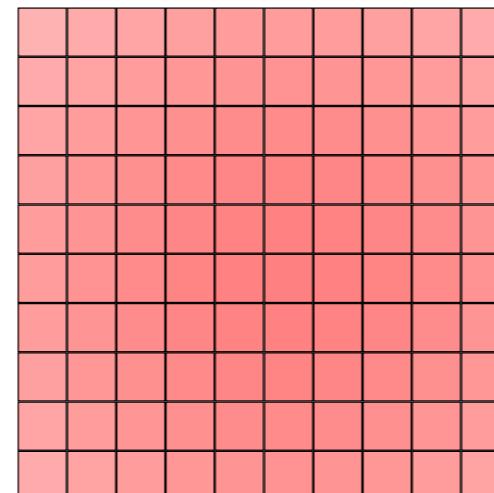

Filtering questions:

$$\mathbb{P}(H_1 \mid E_1 = 0)$$

$$\mathbb{P}(H_2 \mid E_1 = 0, E_2 = 2)$$

$$\mathbb{P}(H_3 \mid E_1 = 0, E_2 = 2, E_3 = 2)$$

Problem: many possible location values for H_i

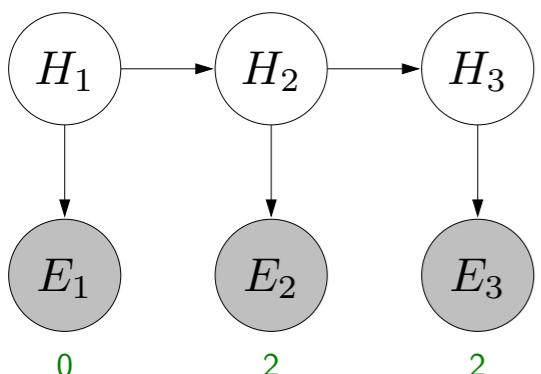

Forward-backward is too slow ($O(n|\text{Domain}|^2)$)...

- Recall that the two common types of inference questions we ask on HMMs are filtering and smoothing.
- Particle filtering, as the name might suggest, performs filtering, so let us focus on that. Filtering asks for the probability distribution over object location H_i at a current time step i given the past observations $E_1 = e_1, \dots, E_i = e_i$.
- Last time, we saw that the forward-backward algorithm could already solve this. But it runs in $O(n|\text{Domain}|^2)$, where $|\text{Domain}|$ is the number of possible values (e.g., locations) that H_i can take on. On this example, $H_i \in \{0, 1, 2\}$ but for real applications, there could easily be hundreds of thousands of values, not to mention what happens if H_i is continuous. This could be a very large number, which makes the forward-backward algorithm very slow (even if it's not exponentially so).
- The motivation of particle filtering is to perform **approximate probabilistic inference**, and leverages the fact that most of the locations are very improbable given evidence.
- Particle filtering actually applies to general factor graphs, but we will present them for hidden Markov models for concreteness.

Beam search for HMMs

Idea: keep $\leq K$ partial assignments (**particles**)

Algorithm: beam search

Initialize $C \leftarrow [\{\}]$

For each $i = 1, \dots, n$:

Extend:

$$C' \leftarrow \{h \cup \{H_i : v\} : h \in C, v \in \text{Domain}_i\}$$

Prune:

$C \leftarrow K$ particles of C' with highest weights

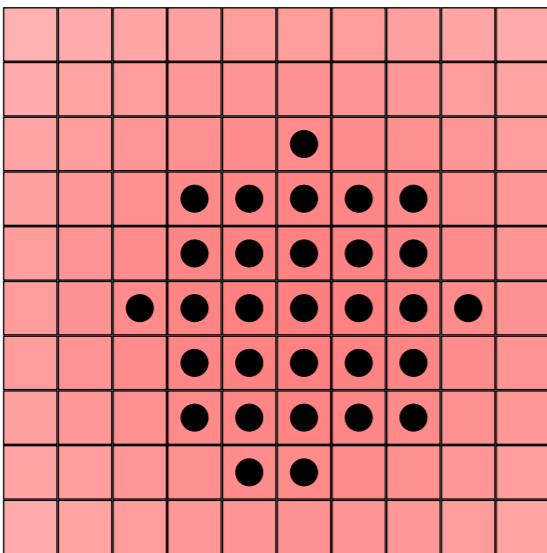

Normalize weights to get approximate $\hat{\mathbb{P}}(H_1, \dots, H_n \mid E = e)$

Sum probabilities to get any approximate $\hat{\mathbb{P}}(H_i \mid E = e)$

[demo: beamSearch({K:3})]

- Our starting point for motivating particle filtering is beam search, an algorithm for finding an approximate maximum weight assignment in arbitrary constraint satisfaction problems (CSPs).
- Since HMMs are Bayesian networks, which are Markov networks, which have an underlying factor graph, we can simply apply beam search to HMMs (for now putting aside the goal of finding the maximum weight assignment).
- Recall that beam search maintains a list of candidate partial assignments to the first i variables. There are two phases. In the first phase, we **extend** all the existing candidates C to all possible assignments to H_i ; this results in $K = |\text{Domain}|$ candidates C' . We then take the subset of K candidates with the highest weight, where the weight of a partial assignment is simply the product of all the factors (transitions, emissions) that can be computed on the partial assignment.
- In the demo, we start with partial assignments to H_1 , whose weights are given by $p(h_1)p(e_1 = 0 | h_1)$. In the next step, we can multiply in factors $p(h_2 | h_1)p(e_2 = 2 | h_2)$, and so on.
- At the very end, we obtain $K = 3$ complete assignments, each with a weight (equal to the joint probability of the assignment and observations). We can normalize these weights to form an approximate distribution over all assignments (conditioned on the observations). From here, we can manually compute any marginal probabilities (e.g., $\mathbb{P}(H_3 = 2 | E = e)$) by summing the probabilities of assignments satisfying the given condition (e.g., $H_3 = 2$).

Beam search problems

Algorithm: beam search

Initialize $C \leftarrow [\{\}]$

For each $i = 1, \dots, n$:

Extend:

$$C' \leftarrow \{h \cup \{H_i : v\} : h \in C, v \in \text{Domain}_i\}$$

Prune:

$$C \leftarrow K \text{ particles of } C' \text{ with highest weights}$$

- Extend: slow because requires considering every possible value for H_i
- Prune: greedily taking best K doesn't provide diversity

Particle filtering solution (3 steps): **propose, weight, resample**

- There are two problems with beam search.
- First, beam search can be slow if Domain is large, since we might have to try every single candidate value h_i to assign H_i . In some cases, we can efficiently generate only the values h_i that have nonzero transition probability ($p(h_i \mid h_{i-1} > 0)$), for example, if we know that h_i must be within a certain distance of h_{i-1} (can't teleport). But if we wanted to track the object to high resolution, there might still be too many values to consider.
- Second, beam search greedily takes the K highest weight candidates at each time step. This could be dangerous, since we might end up with many assignments that are only slightly different, and not truly representative of the actual distribution. You can think of this as a form of overfitting.
- Particle filtering addresses both of these problems. It has three steps: propose, which extends the current partial assignment, and reweight + resample, which redistributes resources on the particles based on evidence.

Step 1: propose

Old particles: $\approx \mathbb{P}(H_1, H_2 \mid E_1 = 0, E_2 = 2)$

$$\{H_1 : 0, H_2 : 1\}$$

$$\{H_1 : 1, H_2 : 2\}$$

Key idea: proposal distribution

For each old particle (h_1, h_2) , sample $H_3 \sim p(h_3 \mid h_2)$.

| h_i | $p(h_i \mid h_{i-1})$ |
|---------------|-----------------------|
| $h_{i-1} - 1$ | 1/4 |
| h_{i-1} | 1/2 |
| $h_{i-1} + 1$ | 1/4 |

New particles: $\approx \mathbb{P}(H_1, H_2, \textcolor{red}{H}_3 \mid E_1 = 0, E_2 = 2)$

$$\{H_1 : 0, H_2 : 1, \textcolor{red}{H}_3 : 1\}$$

$$\{H_1 : 1, H_2 : 2, \textcolor{red}{H}_3 : 2\}$$

- At each stage of the particle filtering, we can think of our set of particles C as approximating a certain distribution.
- Suppose we have a set of particles that approximates the filtering distribution over H_1, H_2 . The first step is to extend each current partial assignment (particle) from (h_1, \dots, h_{i-1}) to (h_1, \dots, h_i) .
- To do this, we simply go through each particle and sample a new value h_i using the transition probability $p(h_i | h_{i-1})$.
- We can think of advancing each particle according to the dynamics of the HMM. These extended particles approximate the probability of H_1, H_2, H_3 , but still conditioned on the same evidence.
- In some cases (e.g., the transitions are Gaussian), sampling h_3 is very easy compared to enumerating all possible of h_3 . (Indeed, the advantages of particle filtering are clearer in continuous state spaces.).

Step 2: weight

Old particles: $\approx \mathbb{P}(H_1, H_2, H_3 \mid E_1 = 0, E_2 = 1)$

$$\{H_1 : 0, H_2 : 1 : H_3 : 1\}$$

$$\{H_1 : 1, H_2 : 2 : H_3 : 2\}$$

Key idea: weighting based on evidence

For each old particle (h_1, h_2, h_3) , weight it by $p(e_3 = 2 \mid h_3)$.

| h_3 | $p(e_3 = 2 \mid h_3)$ |
|-------|-----------------------|
| 0 | 0 |
| 1 | 1/4 |
| 2 | 1/2 |

New particles: $\approx \mathbb{P}(H_1, H_2, H_3 \mid E_1 = 0, E_2 = 1, E_3 = 1)$

$$\{H_1 : 0, H_2 : 1 : H_3 : 1\} \text{ (1/4)}$$

$$\{H_1 : 1, H_2 : 2 : H_3 : 2\} \text{ (1/2)}$$

- Having generated a set of K candidates, we need to now take into account the new evidence $E_i = e_i$. This is a deterministic step that simply weights each particle by the probability of generating $E_i = e_i$, which is the emission probability $p(e_i | h_i)$.
- Intuitively, the proposal was just a guess about where the object will be H_3 , but we need to fact check this guess.
- In this example, we observed $E_3 = 2$, so we need to weight the two particles by $p(e_3 = 2 | h_3 = 1) = 1/4$ and $p(e_3 = 2 | h_3 = 2) = 1/2$, respectively.

Step 3: resample

Old particles: $\approx \mathbb{P}(H_1, H_2, H_3 \mid E_1 = 0, E_2 = 2, E_3 = 2)$

$$\{H_1 : 0, H_2 : 1 : H_3 : 1\} \text{ (1/4)} \Rightarrow 1/3$$

$$\{H_1 : 1, H_2 : 2 : H_3 : 2\} \text{ (1/2)} \Rightarrow 2/3$$

Key idea: resampling

Normalize weights and draw K samples to redistribute particles to more promising areas.

New particles: $\approx \mathbb{P}(H_1, H_2, H_3 \mid E_1 = 0, E_2 = 2, E_3 = 2)$

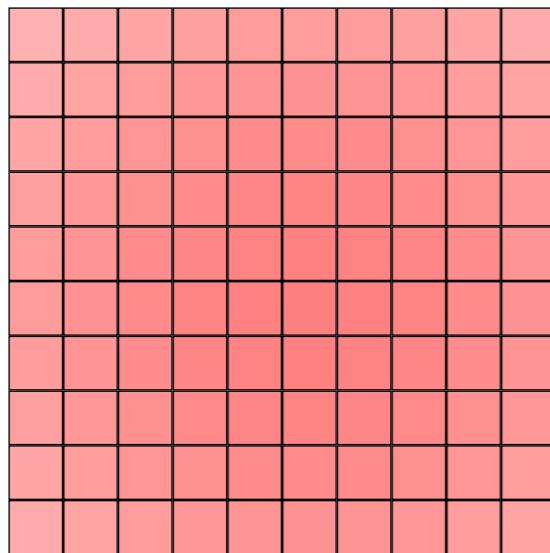

$$\{H_1 : 1, H_2 : 2 : H_3 : 2\}$$

$$\{H_1 : 1, H_2 : 2 : H_3 : 2\}$$

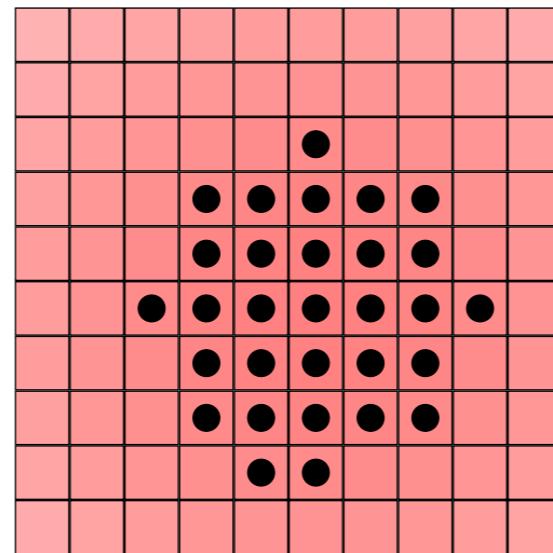

- At this point, we have a set of weighted particles representing the desired filtering distribution.
- However, if some of the weights are small, this could be wasteful. In the extreme case, any particle with zero weight should just be thrown out.
- The K particles can be viewed as our limited resources for representing the distribution, the resampling step attempts to redistribute these precious resources to places in the distribution that are more promising.
- To this end, we will normalize the weights to form a distribution over the particles (similar to what we did at the end of beam search). Then we sample K times from this distribution.
- In this example, we happened to get two occurrences of the second particle, but we might have easily gotten one of each or even two of the first.

Why sampling?

distribution

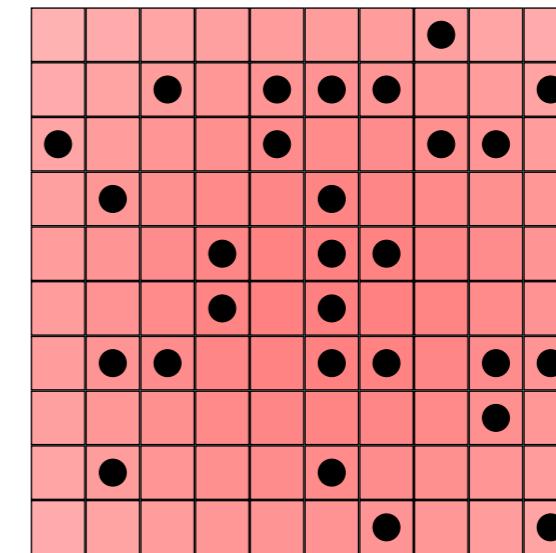

K with highest weight

not representative

K sampled from distribution

more representative

Sampling is especially important when there is high uncertainty!

- You might wonder why we are resampling, leaving the result of the algorithm up to chance.
- To see why resampling can be more favorable than beam search, consider the setting where we start with a set of particles on the left where the weights are given by the shade of red (darker is more weight). Notice that the weights are all quite similar (i.e., the distribution is close to the uniform distribution).
- Beam search chooses the K locations with the highest weight, which would clump all the particles near the mode. This is risky, because we have no support out farther from the center, where there is actually substantial probability.
- However, if we sample from the distribution which is proportional to the weights, then we can hedge our bets and get a more representative set of particles which cover the space more evenly.
- In cases where the original weights much more skewed towards a few particles, then taking the highest weight particles is fine and perhaps even slightly better than resampling.

Particle filtering

Algorithm: particle filtering

Initialize $C \leftarrow [\{\}]$

For each $i = 1, \dots, n$:

Propose:

$$C' \leftarrow \{h \cup \{H_i : h_i\} : h \in C, h_i \sim p(h_i | h_{i-1})\}$$

Weight:

Compute weights $w(h) = p(e_i | h_i)$ for $h \in C'$

Resample:

$C \leftarrow K$ particles drawn independently from $\frac{w(h)}{\sum_{h' \in C} w(h')}$

[demo: `particleFiltering({K:100})`]

- We now present the final particle filtering algorithm, which is structurally similar to beam search. We go through all the variables H_1, \dots, H_n .
- For each candidate $h \in C$, we propose h_i according to the transition distribution $p(h_i | h_{i-1})$.
- We then weight this particle using the emission probability $w(h) = p(e_i | h_i)$.
- Finally, we normalize the weights $\{w(h) : h \in C\}$ and sample K particles independently from this distribution.
- In the demo, we can go through the extend (propose) and prune (weight + resample) steps, ending with a final set of full assignments, which can be used to approximate the filtering distribution $\mathbb{P}(H_3 | E = e)$.

Particle filtering: implementation

For filtering questions, can optimize:

- Keep only value of last H_i for each particle
- Store count for each unique particle

| | | |
|----------------------------------|---|--|
| $\{H_1 : 0, H_2 : 1 : H_3 : 1\}$ | 1 | |
| $\{H_1 : 0, H_2 : 1 : H_3 : 1\}$ | 1 | |
| $\{H_1 : 1, H_2 : 2 : H_3 : 2\}$ | 2 |  1 (2x) |
| $\{H_1 : 1, H_2 : 1 : H_3 : 2\}$ | 2 |  2 (3x) |
| $\{H_1 : 1, H_2 : 2 : H_3 : 2\}$ | 2 | |

- So far, we have presented a version of particle filtering where each particle at the end is a full assignment to all the variables. This allows us to approximately answer a variety of different questions based on the induced distribution.
- However, if we're only interested in filtering questions, then we can perform two optimizations.
- First, in tracking applications, we only care about the last location H_i , and future steps only depend on the value of H_i . Therefore, we often just store the value of H_i rather than the entire trajectory.
- Second, since we have discrete variables, many particles might have the same value of H_i , so we can just store the counts of each value rather than storing duplicate values.

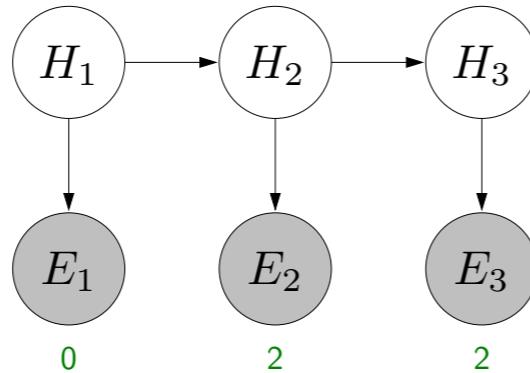

Particle filtering demo

[see web version]

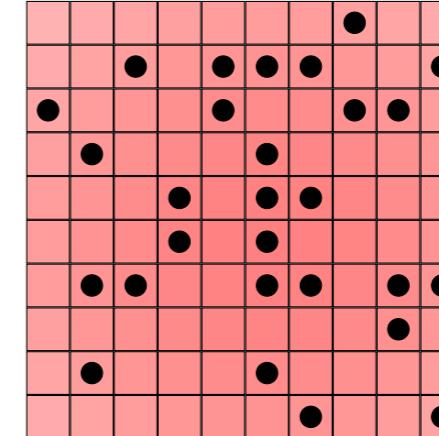

- Now let us visualize particle filtering in a more realistic, interactive object tracking setting.
- Consider an object is moving around in a grid and we are trying to figure out its location $H_i \in \{1, \dots, \text{grid-width}\} \times \{1, \dots, \text{grid-height}\}$.
- The transition distribution places a uniform distribution over moving north, moving south, moving east, moving west, or staying put.
- The emission distribution places a uniform distribution over locations E_i that are within 3 steps (both vertically and horizontally) of the actual position H_i . In the textbox, you can change the emission distribution dynamically (`observeFactor`).
- When you hit ctrl-enter, you can see the noisy sensor readings (visualized as a yellow dot bouncing around).
- If you increase the number of particles, you can see a red cloud representing where the particles are, where the intensity of a square is proportional to the number of particles in that square.
- You can now set `showTruePosition = true` to see the actual H_i that generated E_i . You can see that the cloud is able to track the true location reasonably well, although there are occasional errors.

Summary

$$\mathbb{P}(H_3 \mid E_1 = 0, E_2 = 2, E_3 = 2)$$

- Use particles to represent an approximate distribution

Propose (transitions)

Weight (emissions)

Resample

- Can scale to large number of locations (unlike forward-backward)
- Maintains better particle diversity (compared to beam search)

- In summary, we have presented particle filtering, an inference algorithm for HMMs that approximately computes filtering questions of the form: where is the object currently given all the past noisy sensor readings?
- Particle filtering represents distributions over hidden variables with a set of particles. To advance the particles to the next time step, it proposes new positions based on transition probabilities. It then weights these guesses based on evidence from the emission probabilities. Finally, it resamples from the normalized weights to redistribute the precious particle resources.
- Compared to the forward-backward algorithm, both beam search and particle filtering can scale up to a large number of locations (assuming most of them are unlikely). Unlike beam search, however, particle filtering uses randomness to ensure better diversity of the particles.
- Particle filtering is also called sequential Monte Carlo and there are many more sophisticated extensions that I'd encourage to learn about.
